## Investigating the genetic origin of three Fucus morphotypes using microsatellite analysis

Frida Catharina Skovereng Knoop
Master of Marine Biology, June 2021
Supervisors: Inga Kjersti Sjøtun, Pedro Miguel de Azevedo Ribeiro, Geir Dahle
Department of Biological Sciences, University of Bergen

## Acknowledgements

First, I would like to say thank you Kjersti, for shaping the thesis and for giving me the opportunity to participate in this project. Without exception, you have been so kind and supportive throughout the whole process. Although I only got to explore a small part of the vast world of algae, it surely has been an inspirational and interesting journey full of new learnings. Thank you for your guidance and patience in the field, the lab, and for always answering my questions. I could not ask for a better supervisor, and it has been a pleasure to work with you.

Pedro, thank you for being an excellent co-supervisor. During this thesis, I very much appreciated your positive attitude and patience. Thank you for taking your time to explain the processes behind the molecular work and for guiding me through the statistical part, which I found particularly challenging. During stressful times, your support kept me calm and made sure I did not lose focus. Also, your feedback was very much appreciated.

A special thank you to co-supervisor Geir Dahle at the Institute of Marine Science (IMR) for taking your time to help with the genetic analysis, the ABI Machine, and allele scoring, which was only possible at IMR. I also want to thank you for sharing your knowledge regarding microsatellite analysis, being helpful with the statistics, and providing good feedback. My thesis could not be completed without your help.

Louise, thank you for your guidance during the microsatellite course involving lab procedures such as DNA extraction, PCR, and gel electrophoresis. Despite the extra high demand for laboratory equipment due to the global pandemic crisis, you were able to provide all the necessary equipment so the lab work could be completed in time. Also want to say thank you Kenneth Mæland, for helping with practicalities in the lab. Thank you, Rafael Martín-Martín for contributing with the material from Spain.

Lastly, thank you all for the extra flexibility and countless zoom meetings. I am very grateful that I was able to complete my master thesis, despite the extra challenges that COVID-19 has brought upon us all.

#### Abstract

Species in the Fucus genus play an important ecological role for intertidal communities in the northern hemisphere. Studies in recent years have attempted to unwind the complexity of the Fucus genus. Confusing morphology, intricate phylogeographic history and frequent hybridization are factors that challenge a full understanding of the relationship between species. Therefore, targeting knowledge gaps to understand the fundamental processes behind evolution and the significance for intertidal communities globally is necessary. Also, current climate change imposes potential threats to the survival of intertidal organisms.

This study aims to investigate the genetic relationship between three miniaturized Fucus and the connection to closely related taxa. While Fucus cottonii may have different origins, Fucus spiralis forma nanus is believed to be closely related to Fucus spiralis. Moreover, little is known about the rare Fucus chalonii, only found in a few localities in Northern Spain. However, relationships between $F$. cottonii, F. spiralis f. nanus, and $F$. chalonii and their connection to Fucus guiryi, F. spiralis and Fucus vesiculosus have not been properly investigated. The findings may provide new data for morphotype fucoid and contribute to improving conservation efforts for vulnerable species.

Tissue samples of the Fucus species were collected from several sites in both Norway and Spain. The microsatellite analysis of samples from Norway revealed $F$. cottonii were cloned individuals with close connection to $F$. vesiculosus. Fucus spiralis f. nanus had the closest connection to the nearby sampled F. spiralis. The Spanish samples could not be fully resolved. However, two separate clusters for $F$. chalonii were suggested.

## 1. Introduction

Phaeophycea (brown algae) is a large class of macroalgae that dominate the temperate Arctic and Antarctic coasts (Lüning, 1990; Steinberg, 2019; Wernberg et al., 2019) and currently comprise 2059 described species (Guiry \& Guiry, 2021). Two of the main orders, Fucales (rockweed, wracks) and Laminariales (kelp), are categorized among the largest autotrophs in the marine ecosystem, due to unique features concerning growth, internal transportation, cell communication and tissue differentiation (Bringloe et al., 2020). In comparison to other brown alga, members of the orders Laminariales and Fucales are perennial and long-lived (Lubchenco, 1980; Råberg \& Kautsky, 2007; Zardi et al., 2011; Steinberg, 2019).

Fucales inhabit mainly intertidal communities in the northern hemisphere (Lüning, 1990; Serrão et al., 1999a; Laughinghouse et al., 2015) and are considered essential ecosystem components for the coastal fauna (Coyer et al., 2011). The genus Fucus includes ecologically important foundation species such as Fucus radicans L. Bergström \& Kautsky 2005, Fucus serratus Linnaeus 1753 and Fucus vesiculosus Linnaeus 1753 (Dudgeon \& Petraitis, 2005; Wahl et al., 2011; Duarte et al., 2015; Kautsky et al., 2019). Foundation species provide crucial habitat and nursery ground for other organisms (Steneck et al., 2002; Korpinen et al., 2010), increase the structure complexity (Wikström \& Kautsky, 2007), alter local environmental factors such as light and sedimentation (Bringloe et al., 2020), in addition to increasing primary production (Kautsky et al., 1986; Steneck et al., 2002). Moreover, Fucus also has industrial value through food supplements and commercial compounds (Ferreira et al., 2019; Bringloe et al., 2020; Torres et al., 2020).

Several studies in recent years have attempted to unwind the complexity of the Fucus genus. Its evolutionary history has been interpreted in the light of various mating systems, reproductive strategies, and abilities for hybridization (Mathieson et al., 2006; Neiva et al., 2012; Sjøtun et al., 2017). Especially in the North Atlantic, the evolution and diversification within Fucus is identified as challenging (Coyer et al., 2011). Certain taxa are not recognized as separate species and may represent incipient species evolving into new lineages (Wallace et al., 2004; Cánovas et al., 2011; Neiva et al., 2012; Sjøtun et al., 2017). Therefore, targeting knowledge gaps to understand the fundamental processes behind evolution and the significance for intertidal communities globally is necessary. Furthermore, these studies contribute to amend conservation efforts and management.

To set the scene for my thesis, in the following sections I will provide a brief account of the biology, ecology and evolution of Fucus.

### 1.1 Biology of the Fucus genus

The family Fucaceae presents large morphological variation between taxa (Hardy et al., 1998). At present, the order Fucales has 559 described species, where 18 species belong to Fucacea, and nine to genus Fucus (Guiry \& Guiry, 2021). The Fucus genus is monophyletic and two main lineages are identified (Serrão et al., 1999a). Fucus serratus and Fucus distichus Linnaeus 1767 belong to the first lineage (Coyer et al., 2006a), and the second lineage comprises Fucus ceranoides Linnaeus 1753, Fucus chalonii Feldmann 1941, Fucus cottonii M.C.Wynne \& Magne 1991, F. radicans, Fucus spiralis Linnaeus 1753, F. vesiculosus and Fucus virsoides J. Agardh 1868 (Coyer et al., 2011). Confusing morphology, intricate phylogeographic history and frequent hybridization are factors that challenge the study and full understanding of the species belonging to the second lineage (Neiva et al., 2010; Coyer et al., 2011).

### 1.1.1 Morphology

The general morphology within the Fucacea family consists of parenchymatous thallus, with various forms of holdfast, stipe, branches and air vesicles (Bringloe et al., 2020). In the Fucus genus the terminal buds have dichotomous branching (Kucera \& Saunders, 2008), and on the apical tips, reproductive organs (receptacles) are developed (Monteiro et al., 2012). In general, the nine species in the Fucus genus have olive-green leathery blades, a midrib, seasonal receptacles and adventitious branches that often form during regeneration (Guiry \& Guiry, 2021). However, minor differences are observed in the thallus shape, branching patterns, presence of air vesicles, midrib and holdfast (Table 1).

Table 1. Main characteristics for the ten species in the Fucus genus. $\mathrm{X}=$ Presence of a character. ( X ) $=$ Species which occasionally develop indistinct midribs.

| Species | Holdfast | Thallus | Branching | Adv. branching | Midrib | Vesicles | Receptacles | Reproduction |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| F. ceranoides | X | Flat | Dichotomous | X | X |  | X | Dioecious |
| F. chalonii | X | Narrow, flat | Irregular | X | (X) |  | X | Dioecious |
| F. cottonii |  | Narrow, flat | Dichotomous, irregular | X | (X) |  |  | Vegetative |
| F. distichus | X | Flat | Dichotomous | X | X |  | X | Monoecious |
| F. guiryi | X | Flat, spiraled | Monopodial | X | X |  | X | Monoecious |
| F. radicans | X | Flat | Dichotomous |  | X |  | X | Dioecious |
| F. serratus | X | Flat, spiraled | Dichotomous | X | X |  | X | Dioecious |
| F. spiralis | X | Flat, spiraled | Dichotomous | X | X |  | X | Monoecious |
| F. vesiculosus | X | Flat | Dichotomous | X | X | X | X | Dioecious |
| F. virsoides | X | Flat, spiraled | Dichotomous | X | X |  | X | Monoecious |

### 1.1.2 Life cycle

The mating system is an essential component for understanding the distribution of genetic diversity and gene flow between and within populations (Perrin et al., 2007). Within the Fucus genus there is a wide range of mating systems (Billard et al., 2005; Heesch et al., 2019).

Monoecious species (Table 1), such as F. distichus (Maier \& Muller, 1986; Pearson \& Brawley, 1996), F. virsoides (Serrão et al., 1999a) and $F$. spiralis, develop sperm and oocytes in the same conceptacle and are therefore characterized as hermaphroditic (Monteiro et al., 2012). This mode of reproduction can lead to high levels of inbreeding within a population (Zardi et al., 2011) due to occasional self-fertilization that occurs prior to gamete release (Müller \& Gassmann, 1985). According to Serrão et al. (1996) gamete dispersal among F. spiralis is very restricted, which may contribute to high levels of genetic structuring.

The mating system of the dioecious $F$. vesiculosus (Figure 1) normally depends on two individuals, since sperm and oocytes mature separately in male and female individuals (Wynne \& Bold, 1985; Heesch et al., 2019). Furthermore, species that possess air vesicles conferring the ability for buoyancy may have enhanced dispersal capacity (Tatarenkov et al., 2007). Although rarely observed, a few populations of $F$. vesiculosus in the Baltic Sea have been found to develop vegetatively (Tatarenkov et al., 2005). Studies report high genetic subdivision within a small geographic range for $F$. vesiculosus (Pereyra et al., 2013). Other dioecious Fucus species (Table 1) are F. ceranoides (horned wrack) (Brawley, 1992; Neiva et al., 2010), F. chalonii (Feldmann, 1941), F. radicans (Bergström et al., 2005) and F. serratus (d'Avack \& Tyler-Walters, 2015).

Vegetative reproduction (Figure 2) is characterized for species with asexual mating systems (Neiva et al., 2012), e.g., F. cottonii (Wynne \& Magne, 1991). New individuals, often genetically identical, emerge from adventitious branches (Cotton, 1912).

Figure 1. Life cycle in the dioecious $F$. vesiculosus. Mature male individuals develop receptacles that release antheridia with spermatozoids, and female individuals release oogonia with oocytes. Fertilization takes place when a sperm cell ( n ) and the oocytes ( n ) connect and develop into a diploid zygote ( 2 n ). The zygote will germinate into a new juvenile individual which can repeat the cycle.

Figure 2. Asexual life cycle in F. cottonii. Modified photograph by Kjersti Sjøtun, 2014 (seaweeds.uib.no).

### 1.1.3 Habitat and distribution

Rocky shores are typical Fucus habitat where the species grow in a fucoid zonation (Lubchenco, 1980). In this vertical gradient, abiotic factors such as wave exposure, light, desiccation, temperature and salinity, in addition to competition and predation (biotic interactions), define the species distribution (Zardi et al., 2011). Fucus cottonii is only found in high tide salt marshes in sheltered bays (Wallace et al., 2004), F. ceranoides lives in the upper parts of estuaries (Neiva et al., 2010) and $F$. radicans inhabit brackish waters in the sublittoral zone (Bergström et al., 2005). Fucus spiralis normally grows in the upper littoral zone in areas sheltered from wave exposure (Perrin et al., 2007). Fucus vesiculosus inhabits the littoral zone and F. serratus the lower littoral zone (Lubchenco, 1980), but also in semi-exposed areas (Arrontes, 1993; Nicastro et al., 2013). Due to overlapping habitat, they compete for space in the intertidal zone (Zardi et al., 2011). Fucus virsoides grows in the mid-littoral zone, in sheltered and semi-exposed areas (Verlaque et al., 2019). While some species thrive in sheltered or semi-exposed sites, others like F. chalonii (Feldmann, 1941) and F. distichus (Laughinghouse et al., 2015) grow in very wave-exposed sites.

The geographical distribution of Fucus is extensive as they are considered dominant structural species in the North Atlantic and North Pacific coast (Lüning, 1990; Coyer et al., 2006a; Billard et al., 2010; Coyer et al., 2011). The species in lineage one (consisting of $F$. serratus and F. distichus) has a more northern distribution, F. distichus are located in the North Pacific and North Atlantic (Laughinghouse et al., 2015) and F. serratus is restricted to northeast and northwest Atlantic (Edelstein et al., 1974; Lüning, 1990). Fucus vesiculosus and F. spiralis are generally distributed from the Sub-Arctic to South of Portugal, on the east Atlantic (Wahl et al., 2011), and from Canada to USA on the western margin (Lüning, 1990; Coyer et al., 2006a). However, recent studies have seen F. spiralis and F. vesiculosus in Al-Hoceima, National Park of Morocco (Moussa et al., 2018). Fucus vesiculosus also forms the main sublittoral vegetation on bottom substrate in the Baltic Sea (Ruuskanen \& Bäck, 2002) and is the only fucoid species in the gulf of Bothnia (Torn et al., 2006). Fucus cottonii is located in Europe (Guiry, 2012), the northwest Atlantic (Mathieson et al., 2001) and northeast Pacific (Ruiz et al., 2000). Other Fucus species have more limited distribution e.g., F. ceranoides is endemic to Europe (Neiva et al., 2010), F. radicans to the Baltic Sea (Pereyra et al., 2009; Rinne et al., 2018) and F. virsoides are exclusively found in
the Adriatic Sea (Verlaque et al., 2019). Furthermore, the F. chalonii is only located in a small area in North Spain.

### 1.1.4 Threats to the Fucus genus

In contrast to freshwater systems, the ocean biome is more stable in regards to environmental variabilities (Steele et al., 2019). However, small physiological changes can have a large effect on marine organisms. This is particularly true for intertidal organisms, which already live near their physiological tolerance threshold. According to the latest IPCC report (Bindoff et al., 2019) the ocean temperature has increased by 3.22 ZJ between 1969 - 1993 and 6.28 ZJ from 1993 - 2017, suggesting a two-fold increase in ocean heat uptake. The Institute of Marine Research, has recorded the temperature in the Norwegian coastal waters since 1940, and revealed that the surface layer and deep water temperature was above the normal in 2020 (Havforskningsinstituttet, 2021). Due to a more northern distribution for species in the first Fucus lineage, F. serratus and F. distichus are more exposed to temperature stress (Coyer et al., 2006a) than the species in the second lineage (Cánovas et al., 2011). Lüning (1984) performed a temperature-tolerance experiment on algal species collected on intervals during a 2-year time, in the North sea. After one week exposure time, $F$. serratus upper survival limit was $25^{\circ} \mathrm{C}$ and $F$. vesiculosus and $F$. spiralis limit was $28^{\circ} \mathrm{C}$ (Lüning, 1984). However, other studies demonstrate that temperature changes cause retreat or change of species distribution in the North Atlantic (Lima et al., 2007; Fernández, 2016). In the coast of North Spain, ocean warming is causing the Spanish distribution of $F$. vesiculosus to move westward (Fernández, 2016), and $F$. chalonii is already under potential pressure to become locally extinct. The conservation status for other species with limited distribution, such as $F$. virsoides is listed as vulnerable (V) (Verlaque et al., 2019). In addition, F. cottonii is categorized as near threatened (NT) in the Norway red list (Artsdatabanken, 2015). Furthermore, combining warming with other physiological factors impose even greater threats due to potential cumulative effects. Schonbeck \& Norton (1978) found increasing tissue damage in F. spiralis when exposed to high air temperature, in addition to desiccation and neap tides. In the Baltic Sea there has been a major decline of $F$. vesiculosus, due to ocean acidification combined with elevated sea surface temperature (Graiff et al., 2017). Moreover, global warming can cause increased runoff which will decrease salinity levels in brackish water basins such as the Baltic Sea (Saraiva et al., 2019). As a result, foundation species (such as F. vesiculosus) are exposed to salinity stress that impacts growth
rate (Kinnby et al., 2020). Other threats to photosynthetic organisms are excess nutrients and eutrophication (Sahla et al., 2020). In the Mediterranean there are reports of fucoid algae loss due to destruction of habitat, eutrophication and overgrazing (Thibaut et al., 2015).

### 1.2 Study species

In my thesis, the focus will be on three morphotypes, F. chalonii, F. cottonii, Fucus spiralis forma nanus Kjellmann Batters 1902 and their genetic affinity to close relatives Fucus guiryi Zardi, Nicastro, E.S.Serrão \& G.A. Pearson 2011, F. spiralis and F. vesiculosus (Figure 3). The study species in this thesis are associated with the second lineage in the Fucus genus.

Figure 3. Morphological variation of the six study species. A. Fucus chalonii from Spain, photo taken by Raphael Martín-Martín (2020). B. Fucus cottonii from Indre Eggholmane, Norway (2020). C. Fucus spiralis f. nanus from Ytre Gulo, Norway (2020). D. Fucus guiryi from Bakio, Spain. Photo taken by Kjersti Sjøtun (2016). E. Fucus spiralis from Indre Eggholmane, Norway (2020). F. Fucus vesiculosus from Indre Eggholmane, Norway (2020). Images are not to scale.

### 1.2.1 Three closely related Fucus species

Fucus spiralis, $F$. vesiculosus and $F$. guiryi, the sister species of $F$. spiralis, are genetically closely related (Cánovas et al., 2011; Zardi et al., 2011). Their morphology is also similar, except F. vesiculosus has pneumatocysts (air bladders) for buoyancy (Bringloe et al., 2020), and F. guiryi has receptacles with sterile rim and monopodial branching (Guiry \& Guiry, 2021). While F. guiryi and $F$. spiralis are hermaphroditic (Monteiro et al., 2012), F. vesiculosus is dioecious (Pereyra et al., 2013). Despite contrasting reproductive strategies and frequent hybridization (Engel et al., 2005), these sister species are able to coexist (Monteiro et al., 2012). In the intertidal zone, F. guiryi grows between F. spiralis and F. vesiculosus (Monteiro et al., 2012). Since F. vesiculosus grows on a lower level in the intertidal, it is generally less resilient for desiccation stress (Zardi et al., 2011). The distribution of the three species is largely sympatric. However, F. guiryi has the most southern distribution, from the British isles, along the shores of Iberia and Canary islands, to the Moroccan coasts (Zardi et al., 2011; de Pedro et al., 2019). According to Nicastro et al. (2013) current climate changes have impacted the abundance and distribution of the species in the south.

### 1.2.2 Three small varieties within the Fucus genus

The rare F. chalonii is exclusively found in a few areas in North Spain, growing attached to rock substrate areas in wave exposed sites (described by Feldmann, 1941). This dioecious miniaturized species has irregular to dichotomous branching and develop verrucose receptacles (Gómez-Garreta et al., 2001). Due to limited species distribution, conservation concerns highly apply to this poorly studied species.

Fucus cottonii was first discovered in Ireland (Cotton, 1912). Since then, the species has been given other names until it was revised by Wynne Magne (1991). Fucus cottonii is now considered to be a morphotype with different genetic origin and not a separate Fucus species (e.g., Sjøtun et al., 2017), but is still being referred to by its scientific name. Molecular studies suggest that $F$. cottonii may be a morphotype of $F$. spiralis or $F$. vesiculosus, (Coyer et al., 2006b; Neiva et al., 2012; Sjøtun et al., 2017), or a hybrid between them (Wallace et al., 2004). In contrast to other Fucus species, this moss-like fucoid is missing the holdfast, which may be due to the habitat with reduced water motion (Coyer et al., 2006b), as they grow unattached in high tide sites (Wallace et al., 2004). Another morphological deviation from other Fucus species is irregular branching
pattern (Mathieson et al., 2006) and the lack of receptacles, except for a few populations found in Ireland (Sjøtun et al., 2017). Other places in Europe where F. cottonii is located are Britain (Wynne \& Magne, 1991), France (Loiseaux-de Goër \& Noailles, 2008) and Norway (Wynne \& Magne, 1991). Studies suggest convergent growth forms, due to other miniature species (e.g., F. distichus, F. serratus) associated with salt marsh habitats (Neiva et al., 2012). The uncertain taxonomic status of the $F$. cottonii calls for more information about this entity also out of conservation interest.

Fucus spiralis f. nanus is a smaller version of the hermaphroditic F. spiralis (Hardy et al., 1998; Scott et al., 2001; Mathieson et al., 2006). The species are significantly shorter, have fewer branches, and more units from one singular holdfast when compared with F. spiralis (Scott et al., 2001). In addition, the species develop smaller receptacles than those of $F$. spiralis, which may be seen as a competitive advantage (Norton, 1991). While this is the case, other studies suggest that small thallus size may be related to reproductive disadvantages (Vernet \& Harper, 1980). Earlier studies have observed the species in wave exposed sites in Shetland, Orkney (Powell, 1963) the North East coast of UK, and the west and north coast of Norway (Rueness, 1977; Scott et al., 2000). In this study, F. spiralis f. nanus were exclusively found in the wave exposed locality in Bømlo, Norway. Considering its limited distribution outside the normal habitat (sheltered shores) in Norway, this variety was included in the study in order to investigate its origin.

### 1.3 Evolutionary history and speciation of the Fucus genus

The Fucus genus originated 5.5-2.3 million years ago (Mya), right after the geographical opening of the Bering Strait (Coyer et al., 2011). The opening of the Bering Strait created an arctic passage between the Pacific and Atlantic oceans, allowing species to radiate to new waters (Cánovas et al., 2011). The ancestors of Fucus originated from the North Pacific, and then dispersed and diverged to the North Atlantic around 3-1 Mya (Coyer et al., 2011).

The Fucacea family provides essential community structures in the Northern hemisphere (Cánovas et al., 2011) However, in the South the abundance is significantly smaller, a similarity observed in sister families (Cánovas et al., 2011). Cycles of global ice ages took place 1.8 Mya resulting in closing and opening the trans-oceanic corridor in the Bering Strait up to six times (Cánovas et al.,
2011). In the event of warmer periods the water exchange and flow were higher towards the Atlantic ocean, and therefore a contributing factor for higher species radiation in this direction (Cánovas et al., 2011). In the marine environment there are few barriers that potentially obstruct the gene flow (Cánovas et al., 2011). Thus, full understanding of the mechanism behind speciation is more challenging than in areas with natural barriers.

Several factors contribute to drive marine speciation. Adaptation to environment with various stress factors (desiccation, temperature, wave exposure, competition, predation), biogeographic history, divergent selection and reproductive strategies play important role for how species thrive and evolve (Cánovas et al., 2011). The majority of the Fucacea genera exhibit small species variation, and are therefore considered monospecific (Cánovas et al., 2011). However, the Fucus genus is highly diverse and species rich.

In Europe, the salt marsh version of $F$. cottonii has been found to originate either from $F$. spiralis or $F$. vesiculosus in Ireland (Coyer et al., 2006b; Neiva et al., 2012), or being a hybrid between F. spiralis and F. vesiculosus (Wallace et al., 2004; Coyer et al., 2006b). Fucus spiralis f. nanus, is known from very wave exposed rocky shores (Hardy et al., 1998). Since F. spiralis is associated with sheltered sites, the wave exposed example may be a genetically adapted form. While $F$. cottonii may have different origins, the $F$. spiralis f . nanus is believed to be closely related to F. spiralis. However, relationships between F. cottonii, F. spiralis f. nanus, and their connection to $F$. spiralis and $F$. vesiculosus have not been properly investigated in Norway. Moreover, little is known about $F$. chalonii that was only found in Northern Spain. Due to lack of studies, its origin is not yet fully understood. In addition to exploring the genetic origin of the morphotypes, there is also an important conservation aspect due to their limited distribution in Norway and Spain.

### 1.4 Objectives

Assessing the genetic variation from closely related taxa can provide new genetic data for morphologically separated fucoids and contribute improving conservation efforts for red-list species such as $F$. cottonii and $F$. chalonii.

Using traditional markers (nuclear ITS, mitochondrial DNA) to resolve the evolutionary relationship of species in lineage 2, has been unsuccessful (Zardi et al., 2011; Pereyra et al., 2013). For accurate assessment of genetic diversity in seaweeds, highly polymorphic markers (such as microsatellites) are suggested (Valero et al., 2001). Therefore, for my thesis, genotyping analysis was carried out using eight microsatellite markers developed in previous studies (Engel et al., 2003; Perrin et al., 2007). Morphological description was also accomplished to describe the morphology of each entity and to assess reproductive stage at sampling time.

In order to investigate the genetic relationship between the three morphotypes ( $F$. chalonii, $F$. cottonii, F. spiralis f. nanus) and the connection to closely related taxa (F. guiryi, F. spiralis, F. vesiculosus), the following research questions were addressed:

1) Does $F$. cottonii in Norway originate from $F$. spiralis or $F$. vesiculosus, or is it a hybrid between the two?
2) Is $F$. spiralis f. nanus genetically similar to $F$. spiralis in Norway?
3) Does $F$. chalonii originate from $F$. vesiculosus?

## 2. Material and Methods

### 2.1 Fieldwork

Samples were collected from three locations in southwest Norway (Figure 4) and four locations along the northern coast of the Iberian Peninsula (Figure 5). The samples from Spain were collected by Rafael P. Martín-Martín from the University of Barcelona and Kjersti Sjøtun from the University of Bergen, then stored at the Department of Biological Sciences, University of Bergen. These samples were included as part of the project after agreement with the Spanish group. A total of 304 individuals were collected from 18 sites over a four-year period (details in Table 2).

Figure 4. The three study locations in the Hordaland region, Norway (Source Ocean Data View, 2021).

Figure 5. The four study locations in North Spain (Source Ocean Data View, 2021).

Table 2. Summary of the data collection from north to south and by taxa. $\mathrm{N}=$ number of individuals. Bold type indicates the three morphotypes.

### 2.1.1 Sampling

Specimens of F. cottonii, F. spiralis f. nanus, F. spiralis, F. vesiculosus were sampled in Norway between 2019 and 2020 (Figure 6; Appendix I, A, Figure I). The locations were situated approximately 60 km apart, and a total of 13 samples were collected (Table 2). The red-listed F. cottonii was growing on muddy substrate on the sheltered side in Lygra and Eggholmane. High abundance of loose-laying Ascophyllum nodosum Linnaeus was also observed on these sites. The two common species $F$. spiralis and $F$. vesiculosus, were attached to rocky substrate on the sheltered sites in all three locations. Fucus spiralis f. nanus, was exclusively found in the wave exposed site in Gulo (Bømlo), growing alongside F. distichus. One sample from Indre Eggholmane could not be morphologically distinguished from F. spiralis and $F$. vesiculosus and was therefore named Fucus sp. (N_IEGFsp).

Figure 6. Overview of the three locations (Lygra, Eggholmane, Bømlo) in Norway. Sample IDs are given in table 2 (Source Google maps, 2021).

In Norway, the target species were haphazardly collected by hand along a 10-30 m transect parallel to the shoreline during low tide. A minimum of 0.5 m intervals was used to avoid sampling species from the same clone. Since F. cottonii grows unattached and intertwined, each individual per sample was carefully picked out. The remaining species grew attached and were picked from the holdfast, then placed into plastic bags and stored in cooling bags. Between 8-30 individuals were collected per station, and a few samples from Eggholmane were sampled two successive years (Table 2). Directly after sampling, a clean piece of ca $0.5 \mathrm{~cm}^{2}$ tissue was cut off the tip of each individual, preferably without receptacles for purer DNA extraction. The tissue was placed into 5.0 ml screw-capped tubes filled with silica gel orange (Sigma-Aldrich), then stored dry at $4^{\circ} \mathrm{C}$.

In addition, 2-9 individuals from 10 samples were mounted on herbarium sheets for morphological descriptions (Appendix I, B, Figure II).

Specimens of F. guiryi, F. vesiculosus, F. spiralis and F. chalonii were sampled in Spain between 2016 and 2019. The samples of F. guiryi (originally sampled as F. spiralis var. limetaneus), $F$. spiralis and $F$. chalonii were collected during the summer of 2016 along the Basque coast, and the samples of $F$. vesiculosus were collected in 2019 at Muxía, Galicia. Three of the sites, Talaipe, Bakio, Cobarón, are located $30-50 \mathrm{~km}$ apart on the Eastern side of the Bay (Figure 7). Fucus vesiculosus were not observed at any of these localities. Muxía is situated approximately 500 km further to the west. Fucus chalonii was found attached to rocky substrate in two sites (Cobarón, Talaipe), and $F$. spiralis was growing in the intertidal zone alongside with $F$. chalonii, in Cobarón (Rafael Martín-Martín pers. comm). Fucus vesiculosus was exclusively found in Muxía, whereas F. guiryi was only found in Bakio.

Figure 7. Overview of the sites and the samples from Spain. Sample IDs are given in table 2 (Source Google maps, 2021).

### 2.1.2 Morphological descriptions

Descriptions of morphological characters of the samples, was carried out in the Systematics lab at the Department of Biological Sciences, University of Bergen. A total of 50 individuals of the Norwegian samples were mounted on herbarium sheets and analyzed, in order to describe the morphology of each entity (Appendix I, B, Figure II). In addition, five specimens from the Spanish herbarium were included in the morphological descriptions (Figure 12D-H). Five individuals from each site in Bømlo (IGUFs, ITOFs, YGUFsfn) were measured by hand for morphometric recordings (Table 8). The conditions of the receptacles were also documented, as this may inform about the reproductive stage of the individuals. Total length (cm), leaf width from five branches
(chosen haphazardly), tips with receptacles, tips without receptacles, in addition to presence of adventitious branches, holdfast and midrib was recorded (Figure 8).

Figure 8. Characteristics of the thallus in F. spiralis. The total length was measured from holdfast to the highest point of the thallus.

### 2.2 Laboratory work

The laboratory work was carried out in the DNA lab at the Department of Biological Sciences, University of Bergen. Genomic DNA extraction was performed using the NucleoMag® Plant (Macherey Nagel) on all the 304 individuals. For microsatellite analysis, eight polymorphic microsatellite markers were used (Table 3). Subsequently, the PCR-amplified microsatellites were run on an ABI 3730 DNA Analyzer (Applied Biosystems) at the Institute of Marine Research (IMR) in Bergen and fragments identified using the Genemapper 6.0 software (Applied Biosystems).

Table 3. Characteristics of the eight microsatellite loci used in this study. $\mathrm{Ta}=$ annealing temperature. GenBank accession number DQ314269DQ314273 for the three loci from Perrin et al. (2007) and AY158011-AY158019 for the five loci from Engel et al. (2003).

### 2.2.1 DNA Extraction

For DNA extraction, the NucleoMag ${ }^{\circledR}$ Plant (Macherey Nagel) user manual was followed with small modifications from Fort et al. (2018). The detailed protocol and modifications can be seen in Appendix II, A (Figure III). The DNA extraction is divided into tissue lysis, DNA isolation and DNA quantification. Using magnetic beads for DNA extraction has been identified as an efficient and affordable method for large sampling sets (Fort et al., 2018). Fort et al. (2018) compared several methods for DNA extraction (NucleoMag®, PowerPlant, DNEasy, CTAB) on algae and concluded that the NucleoMag® Plant method produced the highest yield of purified DNA. Marine plants contain a considerable amount of polyphenols and polysaccharides (Fort et al., 2018). Therefore, the four-step washing procedure in the NucleoMag ${ }_{\circledR}$ Plant is extensive due to removing a large proportion of supernatants.

To prepare for DNA extraction (Appendix II, B, Figure IV) the seaweed tissue was homogenized by mechanical disruption using mixer mil TissueLyser II (Qiagen), in order to release the DNA material in the nucleus. According to the protocol, the Lysis Buffer MC1 is added in step 1. However, using a dry sample in the mixing mill provides better disruption of the cells and prevents contamination. The program for grinding the samples was followed according to Næss (2019), two rounds of 20 seconds at 20 Hz . The samples were stored dry in room temperature $\left(21^{\circ} \mathrm{C}\right)$ ready for DNA extraction.

The DNA extraction stage (Appendix II, C, Figure V) starts with tissue lysis, when a mixture of proteinase K , RNase A and buffer MC 1 is added to the homogenized tissue material and incubated for 2 hours at $56^{\circ} \mathrm{C}$. In the following process, the NucleoMag ${ }^{\circledR}$ C-Beads (Macherey Nagel) and binding buffer was added to each sample in a Square-well Block to attach the DNA to the NucleoMag ${ }^{\circledR}$ C-Beads (Macherey Nagel). Thereafter, the Square-well block is placed on a NucleoMag® ${ }^{\circledR}$ SEP (Macherey Nagel) that attracts the beads containing the DNA, while contaminants are removed and discarded by pipetting. In the last step, the DNA is eluted (re-suspended) in $100 \mu 1$ of Buffer MC6 into an Axygen 96-well plate elution tube. The extracted DNA was stored at $4^{\circ} \mathrm{C}$.

To prepare working DNA solutions for PCR, $10 \mu 1$ of the stock DNA extracts were diluted $1: 2$ by adding $10 \mu \mathrm{l} \mathrm{ddH}_{2} \mathrm{O}$. In this process the 96 -well plate is placed on the NucleoMag® SEP (Macherey Nagel), to avoid contamination of NucleoMag® C-Beads (Macherey Nagel). DNA concentration was measured with the Invitrogen QUBIT® fluorometer (ds DNA HS assay kit), to determine if the DNA concentration was adequate. Working DNA solutions were stored at $4^{\circ} \mathrm{C}$.

### 2.2.2 PCR amplification of microsatellite markers

For amplification, each of the eight forward microsatellite primers including a 18 bp-long M13tail, were ordered from Sigma-Aldrich (Appendix II, D, Figure VI). In the PCR-mix one universal M13 primer labeled with a specific fluorescent dye (FAM, VIC, PET, NED) was included (Table 4). The eight primers were assembled into two groups ( 2 x 4 ) post PCR to speed the sequencing step. Properties of the dye are summarized in Table 5.

Table 4. Overview of loci, base pair size, dye and allocated group.

| Primer | Size (bp) | Dye | Group |
| :--- | :--- | :--- | :---: |
| L58 | $103-115$ | FAM | 1 |
| L38 | $169-199$ | FAM | 1 |
| L20 | $120-159$ | VIC | 1 |
| Fsp4 | $128-168$ | PET | 1 |
| L78 | $121-158$ | FAM | 2 |
| L94 | $136-166$ | VIC | 2 |
| Fsp1 | $140-158$ | PET | 2 |
| Fsp2 | $153-194$ | NED | 2 |

Table 5. Summarize the M13 dye properties.

| Dye | Color | Absorption <br> $(\mathbf{n m})$ | Emission <br> $(\mathbf{n m})$ | Intensity |
| :--- | :--- | :---: | :---: | :---: |
| FAM | Blue | 494 | 520 | 100 |
| VIC | Green | 538 | 554 | 100 |
| NED | Yellow | 546 | 575 | 40 |
| PET | Red | 558 | 595 | 25 |

A stock solution of $100 \mu \mathrm{~mol}$ per primer was prepared according to specifications from SigmaAldrich (Appendix II, D, Figure VI). The stock solution of $100 \mu \mathrm{~mol}$ was diluted ten-fold (1:10) by transferring $10 \mu \mathrm{l}$ stock and $90 \mu \mathrm{ldH} \mathrm{H}_{2} \mathrm{O}$ into 1.5 ml Eppendorf tubes. The stock solutions were stored in the freezer $\left(-18^{\circ} \mathrm{C}\right)$. A PCR cocktail (Table 6) was prepared for each primer that was amplified independently. Master mixes comprised of $2.4 \mu \mathrm{lddH} 2 \mathrm{O}, 0.1 \mu \mathrm{l}$ forward primer, $0.2 \mu \mathrm{l}$ reverse primer, $6.1 \mu \mathrm{l}$ AmpliTaq 360 mix (Applied Biosystems) and $0.2 \mu \mathrm{l}$ M13. A total of $9 \mu \mathrm{l}$ PCR cocktail were added into each well of the 96-cassette and $1 \mu$ DNA extraction (1:2 diluted) was added to the 96-cassette with the PCR cocktail.

Table 6. Reaction master mix for one locus.
For a 96 -cassette the mix was multiplied by 100 .

| PCR cocktail |  |
| :--- | ---: |
| Reagents | Volume $(\mu \mathrm{l})$ |
| $\mathrm{ddH}_{2} \mathrm{O}$ | 2.4 |
| Fwd primer | 0.1 |
| Rev primer | 0.2 |
| AmpliTaq 360 mix | 6.1 |
| M13 | 0.2 |
| Total (1 sample) | 9 |
| Total (100 samples) | 900 |

All PCR reactions were run using the C1000 Thermal Cycler (Bio-Rad). Several trials with different temperatures were tested before a midrange annealing temperature of $55^{\circ} \mathrm{C}$ was demonstrating positive results. A two-step PCR was applied. In the first PCR-cycles the M13forward primer was incorporated into the PCR products. In subsequent cycles (touchdown step) it is these products that are the targets for the labelled M13 primers. The same PCR program was selected for all eight primers (Table 7).

Table 7. PCR program used for all eight primers. The annealing temperature (step 3) was set to $55^{\circ} \mathrm{C}$ and 30 cycles.

| PCR Program |  |  |
| :--- | :--- | ---: |
| Step | Degrees $\left({ }^{\circ} \mathrm{C}\right)$ | Time |
| 1 | 95 | 5 min |
| 2 | 95 | 30 s |
| 3 | 55 | 45 s |
| 4 | 72 | 45 s |
| 5 | <-- step $2 \times 30$ |  |
| 6 | 95 | 30 s |
| 7 | 53 | 45 s |
| 8 | 72 | 45 s |
| 9 | $<--$ step $6 \times 7$ |  |
| 10 | 72 | 30 min |
|  | 4 | $\infty$ |

Amplified PCR products were added together for microsatellite genotyping (Table 4). In the first group, $2 \mu 1$ of L58, L38, L20 and Fsp4 amplicons were mixed and in the second group, $2 \mu 1$ of L78, L94, Fsp1 and Fsp2 were mixed. A total mix of $8 \mu \mathrm{l}$ per group was stored at $4^{\circ} \mathrm{C}$ and protected from ambient light prior to microsatellite genotyping. Photo documentation of the PCR process is provided as supplementary material (Appendix II, E, Figure VII).

### 2.2.3 Microsatellite genotyping

Genetic variation for all 304 individuals was evaluated at eight microsatellite loci (Table 3). The genetic analysis of the PCR products was carried out in the laboratory at the Institute of Marine Science (IMR), Bergen. The ABI 3730 DNA analyzer (Applied Biosystems) is a sequencer using capillary electrophoresis to separate and identify fluorescent labelled DNA fragments. The post PCR products were diluted $1: 10$ with $\mathrm{ddH}_{2} \mathrm{O}$ and then $2 \mu$ were transferred to a customized ABI 96-plate. A mixture of Genescan ${ }^{\text {TM }} 500$ Liz standard (Applied Biosystems) and formamide was prepared, and $8 \mu \mathrm{l}$ of this mix was added to each of the samples. The Genescan ${ }^{\text {TM }} 500$ Liz standard is composed of 16 DNA fragments ranging from 35-500 bp making it possible to identify each fragment. The fragments are allocated to pre-determined bins (size range of each allele) with the GeneMapper 6.0 software (Applied Biosystems). PCR processes were repeated for samples with uncertainties, background noise, or missing peaks.

### 2.3 Population genetics analysis

In three loci, three alleles were observed for certain individuals. Since statistical programs are developed for managing two alleles (diploid population) or one allele (haploid population), individuals with three alleles cannot be analyzed correctly. Considering not knowing what caused the three alleles, the three loci (L38, L78, Fsp2) were removed from most of the analyses. The raw genotype data are provided as supplementary material (Appendix III, A, Table A).

### 2.3.1 Quality control of the data

Genotyping errors (null alleles, large allele dropout and scoring failure) that may occur during the PCR process, were identified for all eight loci using software program MICRO-CHECKER version 2.2.3 (Van Oosterhout et al., 2004). LOSITAN 1.0.0 (Antao et al., 2008), a workbench to
detect molecular adaptation based on a $F_{S T}$-outlier method, was used in order to recognize potential loci under selection. The following parameters were applied for all eight loci. CPU Cores: 2, x1000 simulations, confidence interval 0.95 , attempted $F_{S T} 0.528$.

When inbreeding is suspected, the proportion of homozygotes in the population will increase when performing a test for deficit of heterozygotes in Hardy-Weinberg Equilibrium (HWE) assumptions (Wigginton et al., 2005). A global HW test (H1 = Heterozygote deficiency), was computed in the web version of GENEPOP 4.7.5 (Rousset, 2008) in order to explore the level of inbreeding. This was done by measuring the inbreeding coefficients $\left(F_{I S}\right)$ and associated P -values for five loci. A linkage disequilibrium test for each pair of loci in each sample was also calculated in GENEPOP 4.7.5 (Rousset, 2008) in order to search for correlation between alleles at the five loci (Flint-Garcia et al., 2003), using the Fisher's method. Default settings were applied (Marcov chain parameters: dememorization $=1000$, batches $=100$, iterations per batch $=1000$ ). Sequential Bonferroni correction was used in order to correct for type 1 errors, which may occur during multiple statistical tests (Armstrong, 2014).

### 2.3.2 Genetic diversity

F-STAT version 2.9.4 (Goudet, 2003) was used to estimate and test population genetics parameters such as number of alleles $\left(N_{a}\right)$, allelic richness $(A r)$, and Fixation index ( $F_{S T}$ ) and P-values. The allelic richness, which is considered one of the most commonly reported measures of genetic variation, is referred to as the mean number of alleles per locus (Leberg, 2002). FST and P-values were generated after 15300 permutations and adjusted after Bonferroni correction.

GENEPOP 4.7.5 (Rousset, 2008) was used to investigate allele frequency, observed heterozygosity $\left(H_{O}\right)$, expected heterozygosity $\left(H_{E}\right)$, and the inbreeding coefficient $\left(F_{I S}\right)$. A positive $F_{I S}$ value implies heterozygote deficit and negative heterozygote excess within the populations (Wallace et al., 2004). The analyses were calculated per sample and per locus.

### 2.3.3 Genetic structure

GenAlEx 6.5 (Peakall \& Smouse, 2006) was used for principal coordinate analysis (PCoA) via covariance matrix with data standardization, for sampled from Norway and Spain separately.

PCoA was calculated using Nei's genetic distance and represents similarities and dissimilarities between the populations based on allele distribution.

The genetic structure was further analysed in STRUCTURE version 2.3.4 (Pritchard et al., 2000), which allows to explore properties of samples by utilizing multiple locus genotyped information. Analysis was carried out using a burn-in of 500000,1000000 reps of Markov Chain Monte Carlo (MCMC) and 10 iterations. For the samples from Norway and Spain, assumed number of clusters $(\mathrm{K})=2$ to 5 . Previous studies show that $F$. guiryi can be defined by using loci L20 and L78 (Zardi et al., 2011). Therefore, additional STRUCTURE analysis was carried out for the Spanish material with loci L20 and L78, in order to separate $F$. guiryi from $F$. spiralis and $F$. vesiculosus. The web version of Structure Harvester (Earl, 2012) was used for identifying the most likely number of clusters (K) using the method by Evanno et al. (2005), in accordance with the STRUCTURE analyses.

The analysis of molecular variance (AMOVA) was carried out in Arlequin version 3.5.2.2 (Excoffier et al., 2005) in order to investigate the genetic and demographic connections between and among individuals. The populations were grouped after taxa and run with 10000 permutations.

## 3. Results

### 3.1 Morphological descriptions

Morphological descriptions were carried out on 50 individuals from Norway. Photography of the complete Norwegian herbarium are provided as supplementary material (Appendix I, B, Figure II). The material from Spain included five individuals that were mounted on herbarium sheets (Figure 12E-H).

### 3.1.1 Norwegian samples

Fucus cottonii from Indre Eggholmane and Lygra was growing unattached and entangled within each other, and the total length of thallus varied between 1 cm to 2 cm approximately (Figure 9AB). Large abundance of irregular and adventitious branching was seen on most of the individuals.

Figure 9. Morphological traits and scale bar of F. cottonii sampled in Norway. A. Three individuals sampled from Lygra, October 2020. B. Six individuals sampled from Indre Eggholmane, September 2020. Photo by Kjersti Sjøtun, May 2021.

Fucus spiralis from Eggholmane and Lygra was growing attached and had a total thallus length that varied between 10 cm to 25 cm approximately (Figure 10A-F). The specimens had a holdfast, midrib, dichotomous branching and several tips with receptacles. The receptacles were generally in poor condition. One population from Indre Eggholmane, could not be distinguished as F. spiralis or F. vesiculosus and was named Fucus sp. (Figure 10G).

Figure 10. Morphological traits and scale bar of F. spiralis sampled in Eggholmane. A-B. Fucus spiralis (IEGFs12, IEGFs15) sampled from Indre Eggholmane, September 2020. C-D. Fucus spiralis (YEGFs14, YEGFs15) sampled from Ytre Eggholmane, September 2020. E-F. Fucus spiralis (LYGFs1, LYGFs6) from Lygra sampled 2019. G. Fucus sp. (IEGFsp2) sampled from Indre Eggholmane September 2020. Photo by Kjersti Sjøtun, May 2021.

Due to variation in sampling time, it was decided to only carry out morphometric recordings on the samples from Bømlo (Appendix I, B, Figure IID-E, G). The mean number of total length (TL) for the 15 individuals ranged from 4.02 cm to 19.14 cm (Table 8). Fucus spiralis f. nanus was smallest in size ( 4.02 cm ) and had a strong holdfast (Figure 8E-G). Fucus spiralis sampled in Indre Gulo was longest ( 19.14 cm ) (Figure 8AB). The mean number of total leaf width (TLW) was smallest for $F$. spiralis f. nanus $(0.284 \mathrm{~cm})$ and largest for $F$. spiralis from Indre Gulo $(0.682 \mathrm{~cm})$.

Tips with receptacles presence (RP) ranged from 10 to 25 and tips with receptacles absence (RA) ranged from 4 to 35 (Table 8). Fucus spiralis f. nanus had fewer receptacles presence ( $\mathrm{RP}=10$ )
and absent $($ RA $=4)$. Fucus spiralis from Indre Gulo (Figure 11 AB ) was found with most receptacles' presence $(\mathrm{RP}=25)$ and $F$. spiralis from Indre Toska (Figure 11 CD ) had most receptacles' absent $(\mathrm{RA}=35)$. The majority of the $F$. spiralis individuals had receptacles in poor condition. However, F. spiralis f. nanus had receptacles in good conditions, and high abundance of adventitious branching (*).

Table 8. Morphometric recordings of specimens from Bømlo, Norway. $\mathrm{N}=$ number of individuals, TL $=$ mean number of total length, TLW $=$ mean number of total leaf width $\times 5, R P=$ tips with receptacles presence, RA = tips with receptacles absent, and standard deviations (S. D). Asterisk indicates the presence of adventitious branching.

### 3.1.2 Spanish samples

Fucus chalonii was growing attached to rock substrate with a strong holdfast (Figure 12A-E). The total length of thallus varied between 1 cm to 2 cm approximately. The specimens had small thallus with anchoring point from holdfast, a midrib, and dichotomous and irregular branching. One individual from Cobarón was observed with a fertile verrucose receptacle that was relatively
larger than the other tips (Figure 12C). Fucus guiryi had a monopodial branching pattern and more elongated receptacles (Figure F-G). The sterile rim around the thallus could not be seen on the dried samples. A small example of $F$. spiralis had a thallus size of approximately 5 cm , a holdfast, midrib, dichotomous branching, and presence of receptacles (Figure 12H).

### 3.2 Quality control of molecular data

### 3.2.1 Three alleles in three loci

The initial dataset consisted of 304 individuals genotyped at eight microsatellite loci (Table 3). The results of the genotyping demonstrated that 232 individuals were diploid (2n) for all loci (Appendix III, A, Table A). However, 72 individuals were observed with three alleles in three loci (L38, Fsp2, L78). Three alleles were exclusively found in two taxa (F. cottonii, F. vesiculosus). Three alleles in two loci (L38, Fsp2) were found in 29 of 30 F. cottonii individuals sampled in Indre Eggholmane. In addition, 9 of 18 individuals from F. vesiculosus (N_LYGFv) sampled in Lygra, Norway had three alleles in two loci (Fsp2, L78) and 4 of 18 individuals from F. vesiculosus (S_MUXFv) sampled in Muxía, Spain was observed with three alleles of one locus (L78). The complexity of finding three alleles when genotyping presents certain challenges regarding the data analysis, and lack of information on how the alleles are inherited. Therefore, the three loci (L38, L78 and Fsp2) were omitted from most of the analysis.

### 3.2.2 Suspected null alleles and potential loci under selection for all eight loci

All eight loci were quality checked in MICRO-CHECKER for the presence of null alleles and in
LOSITAN for potential influence of selection. Suspected null alleles were detected in two loci (Fsp2, Fsp4). However, comparison of analysis (STRUCTURE, AMOVA and F-STAT) demonstrated minor differences when Fsp4 was removed. One genetic group of F. spiralis disappeared in the Norwegian samples, and F. guiryi disappeared from the Spanish samples. Since the absence of these genetic groups was not relevant for the study questions, it was decided to carry out the rest of the analysis including Fsp4. LOSITAN analysis showed balancing selection for L38 ( $\mathrm{P}=0.0144$ ) and for Fsp2 $(\mathrm{P}=0.0070)$. The remaining six loci were candidates for neutral selection ( $\mathrm{P}>0.05$ ). No candidates were potentially under positive selection. After removing the problematic loci (L30, L78, Fsp2), all subsequent analyses were performed on the remaining five loci.

### 3.2.3 Hardy-Weinberg equilibrium and linkage disequilibrium for five loci

The global test of HWE (Table 9) showed 7 of 18 samples with heterozygote deficit to HWE expectations after Bonferroni correction ( $\mathrm{P} \leq 0.0028$ ). Global values of genetic diversity showed significant deviation from HWE for 15 of 90 exact testes (Appendix III, C, Table C). The global test of linkage disequilibrium (Table 10) showed significant linkage disequilibrium for five locus
pairs after Bonferroni correction ( $\mathrm{P} \leq 0.005$ ). The linkage disequilibrium test per sample at 160 pairs of loci (Appendix III, B, Table B) showed 11 pairs of $F$. spiralis with significant values ( $\mathrm{P} \leq 0.0003$ ), four from N_IEGFs, and seven from N_LYGFs. Furthermore, 74 pairs were not significant $(P>0.0003)$, and for 35 pairs, linkage disequilibrium could not be calculated.

Table 9. Global HWE Exact test for the 18 samples showing P-value and Standard Error (S.E.). Asterisk meaning significant deviation from Hardy-Weinberg expectations after Bonferroni correction; $\alpha=0.05 ; \mathrm{P} \leq 0.0028$.

### 3.3 Genetic diversity

The number of alleles ( $N a$ ) ranged from 6 to 34, with mean number 14.89 (Table 11). The mean number was uniformly low for most taxa $(F$. chalonii $=13, F$. cottonii $=9.5, F$. guiryi $=6$, F. spiralis f . nanus $=6, F$. spiralis $=12,4$ ), except for $F$. vesiculosus (28). The allelic richness $(A r)$ ranged from 1.0730 (N_YGUFsfn) to 4.9189 (N_IEGFv2). Also, the allelic richness was generally
low for most taxa except $F$. vesiculosus. Estimates of observed heterozygosity $\left(H_{O}\right)$ ranged from 0.000 to 0.9933 and expected heterozygosity $\left(H_{E}\right)$ from 0.0133 to 0.7878 (Table 11). The general trend showed 15 of 18 samples with lower observed $\left(H_{O}\right)$ than expected heterozygosity $\left(H_{E}\right)$. Four samples (N_YEGFs1, N_YGUFsfn, S_BAKFg, S_TALFch) had extremly low numbers ( $H_{O}=$ $0.000)$. In contrast, high numbers of $H_{O}$ were found for $F$. cottonii ( $0.9933,0.8000$ ). Fucus spiralis f. nanus (N_YGUFsfn) had lowest $H_{E}(0.0133)$. Furthermore, the inbreeding coefficient $\left(F_{I S}\right)$ (Table 11), were extremely high for N_YEGFs, N_YGUFsfn, S_BAKFg, S_TALFch ( $F_{I S}=$ 1.0000), and very low for $F$. cottonii ( $-1.000,-0.9866$ ). Estimates of the genetic diversity per sample and per loci are provided as supplementary material (Appendix III, C, Table C). Summary statistics per loci for all samples (Appendix III, C, Table D) showed significant P-values for Fsp4 after Bonferroni correction ( $\mathrm{P} \leq 0.01$ ).

Table 11. Genetic diversity estimates per samples genotyped using five microsatellite loci: Number of individuals $(N)$, Number of alleles $(N a)$, allelic richness (Ar), observed heterozygosity ( $H_{o}$ ), expected heterozygosity $\left(H_{E}\right)$, inbreeding coefficient $\left(F_{I S}\right)$.

| Norway | Eggholmane | N_IEGFsp | 8 | 12 | 2.2800 | 0.5500 | 0.3839 | -0.4326 |

The pairwise $F_{S T}$ comparisons gave insight for inter and intraspecific relations, proving significant genetic differentiation after Bonferroni correction ( $\mathrm{P} \leq 0.000327$ ) for 130 of the 150 pairs (Table 12). All pairs of $F$. cottonii showed high and significant genetic differentiation from each other and the other species.

For $F$. spiralis f. nanus significant genetic differentiation was observed for all pairs, except IGUFs, which was geographically the closest site where $F$. spiralis was sampled (Table 12). Comparing the 15 pairs of $F$. spiralis, suggest no significant genetic differentiation for seven pairs. No significant differentiation was found for four pairs of $F$. vesiculosus, including Fucus sp..
$F_{S T}$ values for $F$. chalonii, revealed that seven pairs were not significantly different, including the pairs between them (Table 12). In addition, both $F$. chalonii samples had little genetic differentiation from F. spiralis sampled in Cobarón (COBFs), and F. chalonii from Talaipe showed little genetic differentiation from F. guiryi from Bakio (BAKFg). On the other hand, high and significant genetic differentiation from $F$. vesiculosus sampled in Muxía (MUXFv) was found.

Table 12. Genetic differentiation between all 18 samples. The pairwise $F_{S T}$ (below) and P-value (above) after 15.300 permutations. Indicative adjusted nominal level ( $5 \%$ ) for multiple comparisons was: 0.000327 after standard Bonferroni corrections.

The allele frequency distribution, given by 18 samples, varied across the five loci (Figure 13). Graphs with allele frequency distribution for $F$. cottonii, $F$. spiralis $f$. nanus and for the Spanish samples are provided as supplementary material (Appendix III, D, Figure VIII).

Figure 13. The allele frequency for all 18 samples using five loci. GenAlEx calculated $12 \%$ missing data in S_BAKFg at the locus Fsp4. For S_TALFc, there was $14 \%$ missing data at the locus Fsp4 and L94.

### 3.4 Genetic structure

The principal coordinate analysis (PCoA) for the Norwegian samples (Figure 14) showed four groups. One group included five samples of $F$. spiralis, the second group included $F$. cottonii, F. vesiculosus and Fucus sp., then Fucus spiralis f. nanus was presented as a separate group, again with closest affinity to F. spiralis (N_IGUFs). Fucus spiralis (N_YEGFs1) appeared as a separate
group. This site was sampled from the same locality as N_YEGFs2, but in the previous year (2019) and contained only ten individuals.

Figure 14. PCoA plot for the 13 samples from Norway. The five species are assigned a unique color code. Fucus spiralis (green), F. vesiculosus (blue), F. spiralis f. nanus (pink), F. cottonii (light blue) and Fucus sp. (purple).

The PCoA for the Spanish samples showed three separate groups (Figure 15). Fucus spiralis sampled in Cobarón (S_COBFs) appeared in the same group as F. chalonii sampled in Talaipe (S_TALFch). Fucus chalonii sampled in Cobarón (S_COBFch) was grouping with F. vesiculosus sampled in Muxía (S_MUXFv). On the other hand, F. guiryi appeared to be in a separate group.

Figure 15. PCoA plot for the five samples from Spain. The four species are assigned a unique color code. Fucus spiralis (green), F. vesiculosus (blue), F. guiryi (orange) and F. chalonii (red).

Two STRUCTURE analyses were calculated for Norway and Spain separately. The assumed number of clusters (K) was suggested as four for the Norwegian samples (Figure 16A). Two genetic clusters appeared in F. vesiculosus, and in F. spiralis. A mixture between genetic groups of the two taxa was seen. Fucus spiralis f. nanus, appeared to belong to F. spiralis. Strong genetic structure for $F$. cottonii, and the two samples appeared as an isolated group with no variation within the individuals. However, some genetic connection to $F$. vesiculosus is suggested by the analysis. Fucus sp. from Ytre Eggholmane appeared to be in the same cluster as F. vesiculosus.

In the Spanish samples, the assumed number of clusters (K) are suggested as four (Figure 16B). Within the individuals the STRUCTURE analysis suggested minimal variation, but clear species differentiation was observed. Fucus chalonii appeared in two different clusters. Fucus chalonii from Talaipe was in the same cluster as $F$. spiralis from Cobarón. However, there seems to be a mix of one individual that is suggested to belong to F. chalonii from Cobarón. Fucus guiryi was suggested as a separate cluster, with minor similarities to two individuals in sample 17. Lastly, F. vesiculosus appeared as a genetically isolated group with small variations within the individuals.

Figure 16. STRUCTURE analysis with vertical bars representing different individuals, and the colors are the proportion of genotypes assigned to each genetic group. The number on the x -axis represents samples. $1-7=F$. spiralis, $8=F$. spiralis $f$. nanus, $9=F$. guiryi, $10-13=F$. vesiculosus, $14-15=F$. cottonii, $16-17$ $=$ F. chalonii, $18=$ Fucus sp.. A. The Norwegian samples $(\mathrm{K}=4)$. B. The Spanish samples $(\mathrm{K}=4)$.

The AMOVA analysis (Table 13) supports the STRUCTURE results, showing strong evidence for geographic differences within each species ( $\mathrm{P}=0.0000$ ), and between groups of samples within species $(\mathrm{P}=0.0000)$. Moreover, within populations, individuals are suggested as relatively similar ( $\mathrm{P}=0.7595$ ).

Table 13: AMOVA results for all 18 samples at five loci. Fixation indices: FIS = Among individuals, within populations, $\mathrm{FSC}=$ Among populations, within groups (species), $\mathrm{FCT}=$ Among groups (species), FIT = within individuals. Asterisk indicates significant P-values.

## 4. Discussion

Although several studies have attempted to unwind the complexity of the Fucus genus, the relationships between $F$. chalonii, F. cottonii, F. spiralis f. nanus and closely related taxa (F. guiryi, F. spiralis and F. vesiculosus) have not been properly investigated. The purpose of this thesis is to examine genetic affinity and origin of miniaturized Fucus species by morphological descriptions and microsatellites analysis to answer the following research questions: 1) Does $F$. cottonii in Norway originate from F. spiralis or F. vesiculosus, or is it a hybrid of the two? 2) Is $F$. spiralis f. nanus genetically similar to $F$. spiralis in Norway? 3) Does F. chalonii originate from F. vesiculosus? For the Norwegian samples, the main findings revealed F. cottonii were cloned individuals with close connection to $F$. vesiculosus. The findings concerning $F$. spiralis f. nanus suggested the closest connection to the nearby sampled $F$. spiralis. The Spanish samples could not be fully resolved. However, two separate clusters for $F$. chalonii were inferred.

### 4.1 Discussion of the thesis results

4.1.1 Does $\boldsymbol{F}$. cottonii in Norway originate from F. spiralis or $\boldsymbol{F}$. vesiculosus, or is it a hybrid of the two?
Fucus cottonii is still being referred to by its scientific name, despite being considered as a morphotype with different genetic origin and not a separate species. Studies from Ireland found evidence that $F$. cottonii derived from $F$. spiralis, $F$. vesiculosus or was a hybrid between them (Coyer et al., 2006b; Neiva et al., 2012; Sjøtun et al., 2017). Findings from Iceland (Coyer et al., 2006b) and Maine, USA (Wallace et al., 2004), also reported that $F$. cottonii originated from hybridization between F. spiralis and F. vesiculosus. In Oregon, North East Pacific, F. cottonii most likely originated from Fucus gardneri P.C Silva 1953, which is synonym for F. distichus (Kucera \& Saunders, 2008; Neiva et al., 2012). The results in this thesis support the connection to $F$. vesiculosus.

Fucus cottonii from Indre Eggholmane and Lygra, Norway is suggested to be embedded in the F. vesiculosus cluster (Figure 14). The STRUCTURE analysis (Figure 16A) strongly supports the genetic affinity to $F$. vesiculosus. According to Coyer et al. (2006b), contributions of $F$. vesiculosus genes to the hybrid genome are crucial for local adaptation to salt marsh conditions. Furthermore,
the presence of unique alleles at loci L58, L78 and L94 was used as an argument opposing the hypothesis that $F$. cottonii in Ireland derived exclusively from local F. spiralis (Neiva et al., 2012). Studies found different allele frequency between $F$. cottonii from Oregon and Ireland (Neiva et al., 2012). A comparison with the present results (Figure 17) did not reveal any similarities with the unique alleles found by Neiva et. al (2012).

Figure 17: Comparison of the allele frequency in four loci (L20, L58, L78, L94). A. Fucus cottonii sampled in Norway. B. Fucus cottonii from Yaquina Bay, Oregon (red) and Mulroy Bay, Ireland (green), modified from (Neiva et al., 2012).

Microsatellite genotyping results (Appendix III, A, Table A) revealed that F. cottonii are cloned individuals. According to Sjøtun et al. (2017), F. cottonii sampled in Ireland was not reported as clones, but some were observed with receptacles. The morphological descriptions (Figure 9; Appendix I, B, Figure II) show adventitious branching among specimens from Lygra and Indre Eggholmane, an indication of vegetative reproduction (Figure 2). Also, extreme negative inbreeding coefficients were found (Table 11). A negative $F_{I S}$ suggests that there was an excess of heterozygotes in relation to the expected value. Excess heterozygotes were found in seven out of the eight loci genotyped for LYGFc and in all loci for IEGFc (Appendix III, A, Table A).

Significant heterozygote excess has also been found in muscoides-like Fucus from Maine, USA (Wallace et al., 2004). A study from Antarctica, looking at asexual reproduction and heterozygote selection in demosponge Stylocordyla chupachus, suggested that heterozygote selection would help cloned species maintain some genetic diversity (Carella et al., 2019).

The STRUCTURE analysis (Figure 16A) suggested that within each population the individuals are similar. A closer look at the genotyping results (Appendix III, A, Table A), revealed different genotypes between the specimens from Indre Eggholmane and Lygra, but not within locations. The pairwise $F_{S T}$ (Table 12) points out significant genetic differences when comparing the two locations. Strong evidence for geographic differences within the species was also supported by the AMOVA analysis (Table 13). Although rarely seen, there has been observation of vegetative reproduction among $F$. vesiculosus (Tatarenkov et al., 2005). It could be argued that $F$. cottonii settlements in Eggholmane and Lygra originated from tidal drifts of fragments from F. vesiculosus. The two F. cottonii populations may have emerged by source-sink relationship (Peck et al., 1998), and one individual was able to outcompete the others and establish a population. Or it could be because of a single colonization event by clonal propagation (Serrão et al., 1999b). A study of vegetative reproduction in the introduced red algae Heterosiphonia japonica', reported successful establishment of vegetative propagules in areas that are favorable (Husa \& Sjøtun, 2006).

Three allele genotypes were found in two loci for $F$. cottonii from Indre Eggholmane (Appendix III, A, Table A). Normally diploid species (2n) inherit one allele from each parent. It is not sure how the three alleles were inherited in this study. However, it could be discussed if presence of three alleles was caused by independent mutation that duplicates a region of the genome. Another theory suggests triploid species (3n), with three chromosomes instead of two. Since very high values of observed heterozygosity were seen in both locations (Table 11), it may be the case that three alleles were exclusively expressed in specimens from Indre Egghomane, whereas the third allele was "masked" in those from Lygra. A higher observed heterozygosity than expected heterozygosity (Table 11) could indicate a mix of two previously isolated populations. Polyploidy is an important source of increased genetic diversity and adaptability (Wendel, 2000) and is a frequent feature in plants and more rare in animals (Dufresne et al., 2014). Since triploid animals
are genetically sterile, this has been used in research for controlling the reproduction in salmonids (Benfey et al., 1989). However, triploid F. cottonii would still be able to reproduce asexually. Moreover, three alleles were also found in half of the F. vesiculosus samples from Lygra, and in four out of 18 F. vesiculosus individuals from Muxía (Appendix III, A, Table A). Missing information regarding how the three alleles were inherited challenge to provide answers and fully understand the processes around triploid species. Therefore, further studies are advised.

In summary, the results suggest $F$. cottonii are cloned individuals, genetically similar to F. vesiculosus. Since this study only included two F. cottonii populations sampled from two locations, a connection to F. spiralis in Norway cannot be excluded. Further studies including more samples from several locations are needed to better understand the relationship between F. cottonii and closely related taxa in Norway.

### 4.1.2 Is $\boldsymbol{F}$. spiralis f. nanus genetically similar to $\boldsymbol{F}$. spiralis in Norway?

A study from Yorkshire used pyrolysis mass spectrometry to confirm the status of forma nanus as a small form of $F$. spiralis (Hardy et al., 1998). Also, in the North West Atlantic (Mathieson et al., 2006) and the northeast coast of the UK (Scott et al., 2000), F. spiralis f. nanus is suggested as a miniaturized version of $F$. spiralis. The results in this thesis support the connection to $F$. spiralis.

The STRUCTURE analysis (Figure 16A) revealed that F. spiralis f. nanus was included in the $F$. spiralis cluster, and that the genetic structure was comparable to the closest sampled $F$. spiralis from Indre Gulo. Moreover, pairwise $F_{S T}$ comparisons (Table 12) and the PCoA (Figure 14) also suggest the closest connection to $F$. spiralis from Indre Gulo. It might be the case that $F$. spiralis f. nanus originated from a few migrants from the nearby population of F. spiralis. A study of implications of plant size in monotypic and polytypic populations of $F$. spiralis, suggested possibilities of inter-forma gene flow between $F$. spiralis and $F$. spiralis f. nanus in the UK (Scott et al., 2000).

The population of $F$. spiralis f. nanus appeared to be highly inbred given the extreme high inbreeding coefficient (Table 11). According to Zardi et al. (2011) high levels of inbreeding are seen among hermaphroditic species like F. spiralis. Moreover, extreme low observed
heterozygosity was seen (Table 11) and the microsatellite genotyping (Appendix III, A, Table A) revealed that all individuals were cloned and homozygote. A study from Wallace et al. (2004) suggests that heterozygote deficits could occur naturally among inbred populations. Furthermore, a private allele was observed in one individual (N_YEGFsfn04).

The fieldwork in Bømlo was carried out in August 2021 (Table 2). The morphological recordings (Table 8; Figure 11E-G) revealed more tips with receptacles than without, and that they were in good condition. Fucus spiralis sampled in Bømlo (IGUFs, ITOFs) had less receptacle presence and they were generally in poor condition (Table 8; Figure 11A-D). Based on these findings, it could be argued that the reproductive stage of $F$. spiralis f . nanus appears to be later than nearby F. spiralis. According to Monteiro et al. (2012) asynchronous gamete release constructs major prezygotic barriers. Other studies point out that egg size is impacting survival and that larger eggs were better resourced (Vernet \& Harper, 1980). This was tested for F. spiralis f. nanus by Anderson \& Scott (1998), which found evidence that the small size had reproductive cost in terms of absolute egg size, but not in production of number per unit size. Moreover, the small size is a prominent morphological feature (Table 8; Figure 11E-G; Appendix 1, B, Figure 2G). Small thallus and strong holdfast could be seen as an adaptation trait for exposed sites where wave action is stronger and the desiccation periods longer. Hardy et al. (1998) found F. spiralis f. nanus 5 m above high water mark and suggested that the miniaturized size was caused by increased exposure. Furthermore, a study of transplants of different Fucus taxa in Maine, confirmed that F. spiralis could transform into dwarf embedded thalli within the high intertidal (Mathieson et al., 2006).

In 1977, F. spiralis f. nanus was observed in very wave exposed site along the west- and north coast of Norway as well as in Skagerrak (Rueness). In this thesis, F. spiralis f. nanus was exclusively found in one wave exposed site in Gulo (Figure 6). It might be the case that the abundance of $F$. spiralis f. nanus in Norway has been reduced over time. According to Serrão et al. (1996) gamete dispersal among F. spiralis is very restricted, which may contribute to high levels of genetic structuring. Also, the lack of air vesicles may limit its distribution. Due to limited data, the results in this study could not confirm if the abundance of F. spiralis f. nanus in Norway has been reduced.

To sum up, the result suggests a close connection between $F$. spiralis f. nanus and nearby sampled populations of $F$. spiralis. However, considering the small number of samples, more studies are advised.

### 4.1.3 Does $\boldsymbol{F}$. chalonii originate from $\boldsymbol{F}$. vesiculosus?

Little is known about the rare $F$. chalonii, which has been observed in a few areas in North Spain (Feldmann, 1941). There has been little research about $F$. chalonii, thus its origin is not fully understood. Due to limited material, only a small number of individuals from two sites was included in this thesis (Table 2). Despite few studies and limited material, clear morphological features such as dichotomous branching and biparental reproduction may indicate that $F$. chalonii are connected to $F$. vesiculosus. The results in this thesis could not resolve where $F$. chalonii originated from. However, two separate clusters were suggested.

The PcoA (Figure 15) revealed that Fucus chalonii from Cobarón grouped with F. vesiculosus from Muxía, and F. chalonii from Talaipe grouped with F. spiralis from Cobarón. The STRUCTURE analysis (Figure 16B) supported this by grouping $F$. chalonii from Talaipe with F. spiralis. However, the assumed number of clusters was four and F. chalonii from Cobarón appeared as a separate group. According to the comparison of pairwise $F_{S T}$ (Table 12), high and significant genetic differentiation from $F$. vesiculosus was found. Small morphological variations between $F$. chalonii from Talaipe and $F$. chalonii from Cobarón were seen. Fucus chalonii from Talaipe appeared to be shorter and with smaller leaf width (Figure 12A), than specimens from Cobarón (12B-E). Since $F$. chalonii from Talaipe was collected approximately two months before the specimens from Cobarón (Table 2), seasonal variations could explain the size difference.

In summary, the results suggest little connection between $F$. chalonii and $F$. vesiculosus. However, there are indications that the two $F$. chalonii populations are not in the same genetic cluster. It might be the case that $F$. chalonii in this study was not a separate species, but two morphotypes with comparable morphology to $F$. chalonii. Considering the small number of samples and unclear results, the research question could not be fully resolved. Further studies involving more samples are desirable for better understanding of genetic relations between $F$. chalonii and $F$. vesiculosus.

### 4.1.4 Remarks on three closely related Fucus species

The STRUCTURE analysis (Figure 16A) suggested a large genetic variability for $F$. spirals from Norway. Comparison of pairwise $F_{S T}$ (Table 12) showed that seven of 15 pairs were not significantly differentiated from each other. This indicates a high level of gene flow between the sites. All the F. spiralis samples from Norway are grouped together (Figure 14), except for one sample (N_YEGFs1). The results in this thesis could not reveal why this sample appeared as a separate group. However, low sampling numbers may have been impacting the results.

Fucus vesiculosus was also found with genetic variation within the individuals, but less than in F. spiralis (Figure 16A). Comparison of pairwise $F_{S T}$ (Table 12) showed no significant genetic differentiation between Fucus sp. and nearby sampled F. vesiculosus (IEGFv1). This was supported by the STRUCTURE analysis (Figure 16A). Based on these findings, our results suggest that Fucus sp. is F. vesiculosus. Moreover, high level of inbreeding was seen among the F. spiralis and F. guiryi and not for F. vesiculosus (Table 11). Since F. guiryi and $F$. spiralis are hermaphrodites and $F$. vesiculosus are dioecious (Figure 2), different mating systems would impact the level of inbreeding. High levels of inbreeding for F. guiryi and F. spiralis, and not for F. vesiculosus are supported by other studies (Monteiro et al., 2012; Almeida et al., 2017).

### 4.2 Methodological issues

### 4.2.1 Fieldwork and sampling

Minor suggestions for improving fieldwork and sampling, involves increasing the sample size and more consistent sampling time. Fucus spiralis f. nanus was exclusively found in one location in Norway. Due to COVID-19 travel restrictions, sampling outside of Norway was not possible. The Spanish material was collected a few years earlier, and only parts of the material were available. Additional samples with the emphasis on $F$. chalonii and $F$. spiralis f. nanus would be desirable. Furthermore, morphological descriptions indicated seasonal variations among the sites. More consistent sampling time would be advised so morphological recordings could be carried out on all the Norwegian samples.

### 4.2.2 Laboratory work and statistics

Using NucleoMag® Plant (Macherey Nagel) for DNA extraction on Fucus species provided adequate DNA material for all the 306 individuals, and all the eight microsatellites were amplified successfully. Despite the many advantages of using microsatellite markers, a few issues were encountered.

Three loci (L38, Fsp2, L78) were removed from most of the analysis, due to the appearance of three alleles (Appendix III, A, Table A). Since most population genetic programs are designed for diploid individuals, they do not know how to handle three alleles (Duarte et al., 2015). Another issue related to three alleles, is possibilities for genome duplications or triploid species. Since very high observed heterozygosity was found, this may indicate that more individuals potentially had three alleles. However, they may have been "masked".

Linkage disequilibrium test (Table 10) suggested five pairs of loci being linked. If two loci on a chromosome are very close, they may transmit to the next generation as a pair, even if they are not linked (Selkoe \& Toonen, 2006). Significant pairs were exclusively found in 11 pairs of $F$. spiralis (Appendix III, B, Table B), and not for the other taxa. Zardi et al. (2011) suggested that inbreeding and selfing could induce linkage and Hardy-Weinberg disequilibrium. Moreover, Perrin et al. (2007) found high number of significant linkage disequilibrium between pairs of loci for F. spiralis.

The STRUCTURE analysis for the Spanish samples (Figure 16B) revealed a very similar genetic structure between $F$. spiralis from Cobarón and $F$. chalonii from Talaipe. Since one individual from F. chalonii from Cobarón appeared in population seven and 17, a mix up during molecular work was suspected. However, photo documentation from the DNA extraction process and controlling the raw datafile (Appendix III, A, Table A), excluded the possibility of potential mix up in the lab. It could be argued that low sample numbers may have been a contributing factor. Certain statistical programs (such as MICRO-CHECKER, LOSITAN) were developed years ago and minor problems occurred during installations.

### 4.3 Future perspectives

Despite the arguments above, using microsatellite analysis for investigating the relationship of closely related Fucus taxa has proven to be an efficient method used for separating miniaturized species. Microsatellites have also been used in other studies trying to resolve the genetic affinity for species associated with the second lineage in the Fucus genus (Wallace et al., 2004; Coyer et al., 2006b; Neiva et al., 2012; Sjøtun et al., 2017). Moreover, contribution of genetics analysis in conservation biology is an important factor to counteract extinction of small sized populations (Frankham, 2003).

Relatively low allelic richness was found for all the miniaturized species, except $F$. chalonii sampled in Cobarón (Table 11). Since diversity is considered a key component for natural selection, a decrease in the allelic richness may challenge a population's adaptation potential regarding future environmental changes (Greenbaum et al., 2014). Also, the loss of genetic diversity increases the susceptibility of extinction (Frankham, 2003). As mentioned in section 1.1.4, there are several threats to the Fucus genus. It could be argued how important the three morphotypes in this study are for the intertidal communities. However, from a biodiversity aspect, the morphotypes are highly valuable. On the $9^{\text {th }}$ of June, the Norwegian Nature Diversity Act was entered into force, and the third aspect of the Act states that biodiversity is the world's most important resource (Sørensen, 2010). Organizations such as the Norwegian Biodiversity Information Centre (NBIC) and the International Union for Conservation of Nature (IUCN) aim to preserve biological diversity both locally and globally. According to NBIC (2015), the conservation status of $F$. cottonii was categorized as "Near Threatened" in 2015. Revising the sites where $F$. cottonii was found and updating the status are suggested. Since one sample of $F$. spiralis f. nanus was included in this thesis, does not mean that the species is not found in other sites in Norway. However, F. spiralis f. nanus was not listed in NBIC. Fucus chalonii was also not listed in the IUCN red list. Limited information challenge to provide a complete overview of the distribution. Considering that $F$. chalonii is almost extinct, it may be too late to save this species. However, the data from studying vulnerable species can be useful for conservation of other species. Updated information regarding genetic structure, population size, distribution, and potential threats, are essential for appropriate conservation management and to safeguard species with the potential to become locally extinct.

To unwind the complexity of the Fucus genus it is suggested to further investigate the genetic affinity and origin of miniaturized Fucus species by continuing with morphological descriptions and genetic analysis. Although microsatellite markers are highly versatile, efficient, and affordable in genotyping analysis, other methods such as complete genome sequencing may be able to tackle problems that microsatellites cannot. Moreover, even though there has been increased focus on marine flora in the past years, this thesis highlights the need for regular assessments and conservation status updates concerning Fucus morphotypes in Norway and Spain.

## A. Fieldwork Norway

Figure I. Fieldwork carried out in Bømlo and Eggholmane by Kjersti Sjøtun and Frida Knoop between August and September 2020. A. The boat (Emiliana Huxley) was used to access the sampling areas in Bømlo. B. Sampling F. spiralis from a smaller motorboat in Ytre Eggholmane. C. Seaweed was collected in plastic bags and stored cool during transportation back to the University. D. Collection of $F$. Cottonii on the muddy substrate from Indre Eggholmane. E. Fucus spiralis attached to the rock in Ytre Eggholmane. F. Tissue samples were placed into screw capped tubes with silica gel. G. Wave exposed sampling area in Ytre Gulo, where F. spiralis f. nanus was found.

## B. The Norwegian herbarium

Figure II. Photographs of the 50 individuals that were used for morphometric recordings. Images are not to scale. A. Six F. spiralis individuals sampled from Indre Eggholmane, 2020. B. Three F. spiralis individuals sampled from Ytre Eggholmane, 2019 C. Nine F. spiralis individuals sampled from Ytre Eggholmane, 2020. D. Five F. spiralis individuals sampled from Indre Gulo, 2020. E. Five F. spiralis individuals sampled in Indre Toska, 2020.

Figure II. Continued. F. Five F. spiralis individuals sampled from Lygra, 2020. G. Five F. spiralis forma nanus individuals sampled from Ytre Gulo, 2020. H. Five F. cottonii individuals sampled from Indre Eggholmane, 2020. I. Six F. cottonii individuals sampled from Lygra, 2020.
J. Two Fucus sp. individuals sampled from Indre Eggholmane, 2020.

## Appendix II - Labwork

## A. Detailed protocol

 and suitable plate shakers (see section 2.3). .t is recommended using a Square-wel
Block tor separation (see secion 1.2). Altematively, isolation of DNA can be performed in reaction tubes with suitable magnetic sepparators This protocol is tor manual use and Before starting the preparation:

- Check if RNase A was prepared according to section 3.

1 Homogenize and lyse sample material
Homogenize about $20-50 \mathrm{mg}$ (fresh) or $<10 \mathrm{mg}$ (lyophilized) plant tissue, for example, using mictrotube strips in a mixer mill, and add 500 L. Buffer MC1. Do shaking for $15-30 \mathrm{~s}$. Spin briefly tor 30 as at $1,500 \times g$ to collect any sample from

Optional: If samples contain large amounts of RNA, we recommend the addition
2 Clear lysates
Centrifuge the samples tor 20 min at a tull speed ( $5,600-6,000 \times \mathrm{g}$ ). Remove cap strips.
Transter $400 \mu$. of the cleared lysate (equilibrated to room temperature) to a
Square- well Block. Do not moisten the nims of the well.
$\frac{\text { Note: See recommendations for suitable plates or tubes and compatible }}{\text { magnetic separators section 1.2. }}$

3 Bind DNA to NucleoMag ${ }^{\text {an }} \mathrm{C}$ - Beads Add 30 HL of NucleoMag ${ }^{*} \mathrm{C}$ - Beads and $400 \mu \mathrm{~L}$ Buffer MC2 to each well of the Square-well Block. Mix by pipetting up and down 6 times and shake for 5 min
at room temperature. Alternatively, when processing the kit without a shaker. pipette up and down 10 times and incubate for 5 min at room temperature. Note: NucleoMag" ${ }^{\circ}$--Beads and Buffer MC2 can be premixed. For 96
samples, mix at least $2880 \mu \mathrm{LL}$ of NucleoMage C -Beads with $38,4 \mathrm{~mL}$ of
 ${ }_{B e}$ sure to resuspend the NucleoMag" C-Beads before removing them from the storage bottle. Vortex storage bottle briefly until a homogenous
suspension has been forme Separate the magnetic beads aga Separate the magnetic beads against the side of the well by placing the Square-
wevil Biock on the NNocleoMago sEP magnetic separator. Wait at least 2 min Weif Block on the NucleoMag SEP magnetic separator. Wait at least 2 min
until all the beads have been attractod to the magnets. Remove and discard
supematant by pipeting supernalant by pipeting
Note: Do not difsturt the atracted ine magnetic pellet is not visible in this step. Remove supernatant trom the opposites side of the well
4 Wash with MC3
Remove the Square-well Block from the NucleoMag" SEP magnetic separator. Add 600 pL Buffer MC3 to each well and resuspend the beads by shaking until the beads are resuspended completely ( 5 min). Alternatively, resuspend beads
completely by repeeted pipetting up and down ( 15 times). completely by repeated pipetting un Separate the magnetic beads by placing the Squar-well Block on the
NucleoMag ${ }^{\circ}$ SEP magnetic separator. Wait at least 2 min until all the beads have been attracted to the magnet. Remove and discard supematant by pipetting.
5 Wash with MC4
Remnve the Square-well Block trom the NucleoMag* SEP magnetic zeparator. Add $600 \mu \mathrm{~L}$ Butter MC4 to each well and resuspend the beads by shaking until
the beads are the beads are resuspended completely ( 5 min ). Atternati)
completely by repeated pipetting up and down ( 15 times).
completely by repealed pipeting up and down (15 tmes).
Separate the magnetic beads by placing the Square-well Block on the
NucleoMag" been attracted to the magnet. Remove and discard supematant by pipetting.

6 Wash with $80 \%$ ethano
Remove the Square-well Block from the NucleoMag" SEP magnetic separator Add $600 \mu L .80 \%$ ethanol to each well and resuspend the beads by shaking unt
the beads are resuspended completely ( 5 min) Alternatively, resuspend beads completely by repeated pipetting up and down ( 15 times).
Separate the magnetic beads by placing the Square-well Block on the Cleomag" SEP magnor. Wait at least 2 min until all the beads ha been atracted to the magnet. Remove and discard supermatant by pipetting. 7 Wash with MCS
! Leave the Square-well Block on the NucleoMag" SEP magnetic separator. - Note: Supernatant is colorless, magnetic bead pellet is clearly visible. Gently add $600 \mu$ LL Buffer MC5 to each well and incubate for $45-60 \mathrm{~s}$ while the
beads are still atrracted to magnets. Then aspirate and discard the supernatant. Note: Do not resuspend the beads in Wash Buffer MC5. This step is to and eliminates a drying step!
8 Elution
Remove the Square-well Block from the NucleoMag ${ }^{9}$ SEP magnetic separator: Add desired volume of Butfer MC6 ( $50-200 \mu$ LL) to each well of the Squar-well
Bilcck and resuspend the beads by shaking $5-10$ min at $56{ }^{\circ} \mathrm{C}$. Alteratively. esuspend beads completely by repeated pipetting up and down and incubal or $5-10 \mathrm{~min}$ at $56{ }^{\circ} \mathrm{C}$.
Separate the magnetic beads by placing the Square-well Block on the
NucleoMag ${ }^{\circ}$ SEP magnetic separator. Wait at least 2 min until all the beads IucleoMag" ${ }^{\circ}$ SEP magnetic separator. Wait at least 2 min until all the beads
ave been attracted to the magnets. Transter the supermatant containing the have been atrracted to the magnets. Tran
puified genomic DNA to the Elution Plate.
Note: Yield can be increased by $15-20 \%$ by using pre-warmed elettion
buffier ( $555^{\circ} \mathrm{C}$ ) or by incubating the bead/elution buffer suspension at $55{ }^{\circ} \mathrm{C}$
for 10 min.
$\qquad$

Figure III. In the user manual of NucleoMag® Plant (Macherey Nagel), the detailed protocol was followed with the following modifications. In step 1, the tissue samples were homogenized dry instead of with buffer 1, and proteinase K and RNase A were added to buffer MC1. For master mix $1,520 \mu \mathrm{l}$ were distributed into the wells, instead of $523 \mu \mathrm{l}$, because the Repetman® is limited to 0.5 decimals. The incubation time was 2 h instead of 30 min at $56^{\circ} \mathrm{C}$. In step 2 , the samples were centrifuged for 20 min at $4^{\circ} \mathrm{C}$ instead of at room temperature. For mixing, an automatic 12-pipette was used to pipette up and down 15 times. In step $8,100 \mu$ l of buffer MC6 was added and then incubated in the oven for 10 min at 100 rpm .

## B. Preparing for DNA extraction

Figure IV. A. Tissue samples in a screw capped container with silica gel. B. Transferring subsample of the tissue into 96 -cassette wells using a tweezers that was sterilized between each sample to avoid contamination. C. Fucus spiralis subsample in 8 -tube wells with the 3 mm tungsten ball. D. TissueLyser machine in process of grinding the subsamples. E. Less tissue in the subsample from F. cottonii due to the small size. F. Homogenized subsample ready for DNA extraction.

## C. DNA extraction stage

Figure V. A. All components of the NucleoMag® Plant Kit were sorted in chronological order and additional tools such as measuring cylinders were prepared. B. In step 1, the reagents were mixed into a 60 ml glass container and distributed out into the wells with Repetman®. C. The IKA® KS 4000 i Control was used for incubation at $56^{\circ} \mathrm{C}$ for two hours. D. After incubation, the samples were centrifuged for 20 min at $4^{\circ} \mathrm{C}$. E. After centrifugation, $400 \mu \mathrm{l}$ of cleared lysate were transferred into a square-well block. F. The Repetman® were used to distribute the C-beads mix into the Square-well Block with the cleared lysate. G. An automatic 12-pipette was used to mix by pipetting up and down 15 times. H. When the Square-well Block was placed on the NucleMag® SEP, the beads were attracted to the magnet which formed a ring with the beads and DNA. I. The reagent was transferred into disposable reagent reservoirs when using the multiple 12 -pipette. J. Approximately $100 \mu 1$ of purified DNA was transferred into the 96 -cassette.

Figure VI. Technical data sheet (Sigma-Aldrich) with specifications for stock solutions.

## E. PCR process

Figure VII. A. PCR components were assembled while reagents were thawing in an Eppendorf tube rack. Due to AmpliTaq 360 mix (Applied Biosystems) hot-start enzymes the work could be carried out at room temperature. B. The Repetman ${ }^{\circledR}$ with a $500 \mu 1$ pipette tip was used to distribute $9 \mu 1$ of the cocktail mix into an Axygen 96-plate. C. Reagents for the PCR process were stored in a Sarstedt box (1.5-2.0 ml tubes) in the freezer $-18^{\circ}$ C. D. $1 \mu$ of 1:2 diluted DNA were added to the cocktail mix. E. A total of $10 \mu \mathrm{l}$ PCR mix was used in the C1000 Thermal Cycler (Bio-Rad). F. Multiple 8-pipette were used to transfer $2 \mu \mathrm{l}$ postPCR products into a new 96-cassette.

## Appendix III - Data

## A. Raw data

Table A. Microsatellite genotyping results for all 304 individuals at eight loci. The individuals are assigned a specific ID. The first capitalized letter describes the sample region ( $\mathrm{N}=$ Norway, $\mathrm{S}=$ Spain), the following three capitalized letters indicates sample location ( $\mathrm{LYG}=\mathrm{Lygra}$, $\mathrm{IEG}=$ Indre Eggholmane, YEG = Ytre Eggholmane, IGU = Indre Gulo, YGU = Ytre Gulo, ITO = Indre Toska, thereafter two letters describes name of the species $(\mathrm{Fch}=$ Fucus chalonii, $\mathrm{Fc}=$ Fucus cottonii, $\mathrm{Fg}=$ Fucus guiryi, $\mathrm{Fsfn}=$ Fucus spiralis forma nanus, $\mathrm{Fs}=$ Fucus spiralis, $\mathrm{Fv}=$ Fucus vesiculosus), and the two number on the end describes the number of individual sampled.

## B. Linkage disequilibrium

Table B. P-values and standard error (S.E.) for 16 samples and pairs of loci. Fucus cottonii (N_IEGFc, N_LYGFc) was removed since there is no connection with the other samples due to asexual reproduction (clones). Asterisk indicates significant P -values after Bonferroni correction; $\alpha=0.05 ; \mathrm{P} \leq 0.0003$ ).

## C. Summary statistics

Table C. Estimates of the genetic diversity for the complete dataset (per sample and per loci). Number of individuals ( N ), number of alleles ( Na ), allelic richness ( Ar ), observed heterozygosity $\left(H_{O}\right)$, expected heterozygosity $\left(H_{E}\right)$, standard deviation (S.D), inbreeding coefficient ( $F_{I S}$ ). Asterisk indicates significant P values after Bonferroni correction; $\alpha=0.05 ; \mathrm{P} \leq 0.0028$. $\mathrm{NA}=$ monomorphic.

## D. Allele frequency

The allele frequency distribution for $F$. cottonii (Figure VIII, A) showed different allele sizes between specimens from Eggholmane (N_IEGFc) and Lygra (N_LYGFc), in all loci except L58. Fucus spiralis f. nanus (N_YGUFsfn) allele frequency distribution was almost identical to F. spiralis (N_IGUFs, N_ITOFs), for all loci except Fsp4 (Figure VIII, B). For the Spanish samples (Figure VIII, C), there is more variation in the allele frequency distribution between the taxa. However, F. chalonii from Talaipe (S_TALFch) appear as more like F. spiralis from Cobarón (S_COBFs), and F. chalonii from Cobarón (S_COBFch) is presented as more similar to $F$. vesiculosus sampled in Muxía (S_MUXFv).

A

Figure VIII. Bar graph with allele frequencies at five microsatellite loci. A. Fucus cottonii from Indre Eggholmane and Lygra. B. Fucus spiralis f. nanus and F. spiralis, from Bømlo, Norway. C. Fucus chalonii, $F$. guiryi, $F$, spiralis and $F$. vesiculosus from Spain.

## E. Evanno table outputs

Table E. Analysis of the Norwegian samples from Structure Harvester suggesting K=4.
