Author contributions: MO conceived and planned the experiment, VV and KK designed the climate grid, set up the field localities and designed the field experiment, LT performed the field work, SLO, LT, KK and MO analyzed the data, SLO and LT wrote the manuscript. All authors commented on earlier versions of the manuscript.

1 Abstract

2

3 Seedling recruitment is a critical life history stage for trees, and successful recruitment is tightly linked
4 to both abiotic factors and biotic interactions. In order to better understand how tree species
5 distributions may change in response to anticipated climate change, more knowledge of the effects of
6 complex climate and biotic interactions is needed. We conducted a seed sowing experiment to
7 investigate how temperature, precipitation and biotic interactions impact recruitment of Scots pine
8 (*Pinus sylvestris*) and Norway spruce (*Picea abies*) seedlings in southern Norway. Seeds were sown
9 into intact vegetation and experimentally created gaps .To study the combined effects of temperature
10 and precipitation, the experiment was replicated across twelve sites, spanning a natural climate
11 gradient from boreal to alpine and from sub-continental to oceanic. Seedling emergence and survival
12 were assessed 12 and 16 months after sowing, respectively, and above-ground biomass and height was
13 determined at the end of the experiment. Interestingly, very few seedlings were detected in the boreal
14 sites, and the highest number of seedlings emerged and established in the alpine, indicating that low
15 temperature did not limit seedling recruitment. Site precipitation had an overall positive effect on
16 seedling recruitment, especially at intermediate precipitation levels. Seedling emergence,
17 establishment and biomass were higher in gap plots compared to intact vegetation at all temperature
18 levels. These results suggest that biotic interactions in the form of competition may be more important
19 than temperature as limiting factor for tree seedling recruitment in the sub- and low-alpine zone of
20 southern Norway.

24

25 Introduction

26 All populations depend on successful recruitment for their long-term persistence. Recruitment is thus a
27 key life history event that involves several phases and processes: flowering, pollination, seed
28 maturation, seed dispersal, seed germination and survival of seedlings, all of which are influenced by
29 both abiotic (e.g. climatic) conditions and biotic interactions (Grubb 1977; Kitajima and Fenner
30 2000; Turnbull et al. 2000; Bansal and Germino 2010). In harsh environmental conditions such as the
31 alpine it can take a long time from seedling emergence to establishment. Thus, for trees in this
32 environment, abiotic and biotic conditions affecting seedlings must prevail for several seasons to
33 assure successful recruitment (Juntunen and Neuvonen 2006). Knowledge of the relative importance
34 of abiotic and biotic factors affecting early life-stages and variation across ecotones is thus paramount
35 to understand the recruitment dynamics of tree species in various environments.

36 Abiotic factors are often considered the most important determinants of plant recruitment in
37 climatically harsh and cold environments, and seedling establishment has been shown to be strongly
38 affected by both temperature and precipitation in these habitats (Smith 1994; McCarty 2001). In
39 general, increasing temperature is assumed to favour plant recruitment in low-temperature
40 environments (Fenner and Thompson 2005). In boreal conifer trees (e.g. *Pinus* and *Picea* species),
41 germination typically peaks at temperatures slightly above 20 °C, while periods with temperatures
42 below 15°C during the growing season limit seed germination (Black and Bliss 1980; but see Milbau
43 et al. 2009). Precipitation is also known to have a direct positive effect on seedling establishment in
44 dry environments, and drought can lower seedling survival drastically (McCarty 2001; Walther et al.
45 2002). However, the effects of precipitation on recruitment are hard to predict as these depend on the
46 amount, timing and predictability of the rainfall (Fay and Schultz 2009).

47 Biotic interactions also play a key role in tree seedling emergence, establishment and survival (Ohlson
48 and Zackrisson 1992; Hörnberg et al. 1997). A recent study on alpine plants found that once a plant
49 seedling has germinated in a suitable microhabitat, biotic interactions become one of the major drivers
50 of establishment success (Olsen and Klanderud 2014). Accordingly, seedling responses to

51 neighbouring vegetation are an important aspect of regeneration and possibly of the ensuing structure
52 of tree stands and forests (Maher and Germino 2006). However, the effects of biotic interactions are
53 themselves known to vary with abiotic conditions. The stress-gradient hypothesis proposed by
54 Bertness and Callaway (1994) suggests that the magnitude of biotic interactions differ along gradients
55 of abiotic environmental stress: facilitation and competition are expected to dominate at high and low
56 stress levels, respectively (Callaway et al. 2002). Hence, competition should be more important as a
57 determining factor for recruitment in habitats with warm and wet conditions compared to habitats that
58 are relatively cold and dry, where facilitative interactions more likely prevail.

59 In this study we investigated the interactive effects of climate and biotic interactions on the
60 recruitment and growth of two common boreal tree species, Scots pine (*Pinus sylvestris* L.) and
61 Norway spruce (*Picea abies* (L.) Karst.) in southern Norway. Seeds of both species were sown into
62 intact vegetation and bare-ground gaps. Scots pine and Norway spruce are dominant forest tree species
63 within the boreal zone of Eurasia and both species are native to Norway and known for their wide
64 ecological range (Ohlson and Zackrisson 1992; Seppä et al. 2009). Creating experimental gaps in
65 natural and semi-natural habitats is a standard method for examining the importance of biotic
66 interactions from neighbouring plants (Aarssen et al 1990) and has proven useful for studying
67 interspecific interactions (Diaz et al. 2003). The experiment was replicated within a unique climate
68 “grid” consisting of a natural temperature gradient (alpine-boreal) repeated over four levels of
69 precipitation (continental-oceanic) (see Meineri et al. 2013, 2014). The climate grid encompasses the
70 tree line ecotone, in which dynamics of upward tree migration has been extensively studied in a
71 climate warming perspective (Kozłowski et al. 1991; Kullman 2002; Körner and Paulsen 2004;
72 Holtmeier and Broll 2005). Despite comprehensive studies of the tree line ecotone, knowledge is still
73 lacking on the relative importance of abiotic and biotic factors as determinants of tree recruitment in
74 alpine and sub-alpine environments. Understanding the factors impacting successful recruitment is a
75 fundamental step towards understanding tree line dynamics in a changing climate.

76 We have addressed the following questions: 1) How does the emergence, establishment and growth of
77 pine and spruce seedlings vary with temperature and precipitation? 2) How do biotic interactions from

78 the standing vegetation sward impact seedling recruitment and growth? 3) How does the effect of
79 biotic interactions vary along the climate gradient? We expected higher seedling emergence and
80 establishment under warm and wet conditions. Further, we hypothesized that the effect of gap
81 formation (i.e. release from biotic interactions) on seedling emergence and establishment would
82 become increasingly positive with increasing temperature, in accordance with the stress-gradient
83 hypothesis. For cold sites we expected to find a negative gap effect, as neighbouring plants may
84 provide shelter from harsh environmental conditions such as wind, drought and frost (Maher and
85 Germino 2006). As climatic conditions are likely to have a significant impact on plant allocation, we
86 examined the biomass of seedlings at the end of the experiment. We expected seedlings to grow taller
87 and heavier with increasing temperature and precipitation. Finally, we hypothesized that seedlings in
88 intact vegetation, experiencing more intense competition for light, would invest relatively more in
89 height growth than seedlings in gaps.

90

91 Methods

92 *Study area, study species and experimental design*

93 The seed sowing experiment was conducted within a unique climate grid consisting of a natural
94 temperature gradient replicated four times along a precipitation gradient stretching from the relatively
95 continental inland towards the oceanic coast in southern Norway (see map in Supplementary Material,
96 Fig. S1). The grid allows for the independent combination of three levels of summer temperature
97 [means of the four warmest months: 6.5°C (alpine), 8.5°C (sub-alpine) and 10.5°C (boreal)] with four
98 levels of precipitation [600 mm, 1200 mm, 2000 mm and 2700 mm] across twelve sites (Fig. S1 and
99 Table 1; see also Meineri et al. 2013, 2014).

100 The twelve study sites were all located in semi-natural grasslands on calcareous bedrock supporting
101 high fine-scale plant diversity. The four alpine sites were situated in the low-alpine zone, the four sub-
102 alpine sites at or just below the tree line, and the boreal sites were situated in or near forested areas. In
103 this paper the term tree line refers to the transition from the uppermost closed forest to the treeless

104 alpine vegetation (Körner and Paulsen 2004; Batllori et al. 2009). Besides their climatic attributes,
105 sites were selected to keep vegetation type, geology and land-use as constant as possible to facilitate
106 comparison among sites. The mean vegetation height in the sites increased with increasing
107 temperature from 6.5 cm in the alpine sites to 9.7 cm in the sub-alpine and 15.3 cm in the boreal sites
108 (Olsen et al. submitted). Further details on vegetation characteristics and site selection criteria are
109 described in Meineri et al. (2013, 2014).

110 Five experimental blocks were established in each of the study sites, with four study plots of 25 × 25
111 cm positioned in a grid within each block. These four plots were randomly assigned to one of two
112 vegetation treatments for each of the species: controls with intact vegetation and gaps where
113 vegetation and roots were removed. In total there were 240 study plots; 120 for each species.

114 In spring 2010, 50 seeds were sown in each plot. All seeds used in the experiment were bought from
115 the public seed supplier “Skogfrøverket” in Lillehammer, Norway, and stored at -20 °C prior to
116 sowing. Seeds were scattered evenly on the bare soil of the gap plots and onto the intact vegetation in
117 the control plots. To prevent seeds from being blown or washed away from the gap plots seeds were
118 pressed down a few millimetres into the soil surface, but not covered. Sites were fenced to prevent
119 animal trampling and disturbance, and the grassland sward was cut approximately 5 cm above ground
120 level in late August to mimic biomass removal by abundant free-roaming domestic and wild ungulates
121 in the area. Otherwise seedlings were left undisturbed.

122 Seedling recruitment was assessed by recording seedling emergence, establishment and growth. The
123 number of seedlings was counted 5, 12 and 16 months after sowing. Due to low over-winter mortality
124 (<5%) we defined the emergence phase as the first 12 months after sowing, followed by the
125 establishment phase from 12 to 16 months. After the last count (16 months after sowing) the
126 aboveground part of all seedlings was harvested. The harvested seedlings were stored in paper bags
127 and dried at 80°C until constant weight. The height (total length from the original emerging point to
128 the apical meristem) and aboveground dry-weight biomass of all seedlings were measured
129 individually.

130 *Statistical analyses*

131 Effects of climatic variables and creation of gaps on tree seedling emergence, establishment and
132 growth were examined using linear mixed-effects models. The boreal sites were omitted from these
133 analyses due to the very low numbers of seedlings that emerged (Fig. 1). Temperature (from cold to
134 warm: alpine, sub-alpine), precipitation (from dry to wet: 1-4) and treatment (gap versus intact
135 vegetation) were used as fixed factors. To account for the nested design, we estimated random
136 intercepts for blocks nested in sites. Poisson distributions were used for seedling emergence and
137 establishment, and normal distributions were found suitable for seedling height and biomass variables.
138 Likelihood ratio (LR) tests were used to select the final models. Markov Chain Monte Carlo (MCMC)
139 estimation with 10.000 iterations was used to assess variable significances for the models assuming
140 normal distribution. Separate mixed-effects models were run for each tree species. All statistical
141 analyses were performed in R version 2.15.2 (R Development Core Team 2012) using R Studio
142 Version 0.96.331 (RStudio, Inc). We used the package lme4 (Bates et al. 2012) for the mixed effects
143 models and LanguageR (Baayen 2011) for the Markov Chain Monte Carlo estimations.

144

145 **Results**

146 Overall, emergence and growth patterns were similar for pine and spruce. In total 1226 pine seedlings
147 and 1138 spruce seedlings emerged during the first 12 months. Numbers of emerged seedlings per plot
148 ranged from 0 to 41 for pine, and from 0 to 44 for spruce, with a median of 9 and 10, respectively.
149 After 16 months, at the end of the second growing season, 900 pine and 922 spruce seedlings had
150 established and were harvested.

151 The number of emerged seedlings in intact vegetation decreased with increasing temperature and
152 increased with precipitation (Fig. 1a and b). Mean seedling emergence per plot was 2-3 times higher in
153 alpine than sub-alpine sites for both species (Fig. 1a and b). Seedling emergence increased with site
154 precipitation regardless of site temperature, but more strongly in sub-alpine (pine: coef=1.98, p<0.01
155 for precipitation level 3 and coef=1.73, p<0.01 for precipitation level 4; spruce: coef=1.49, p<0.01 for

156 precipitation level 3 and $\text{coef}=1.63$, $p<0.01$ for precipitation level 4) than in alpine (pine: no
157 significant difference, $p>0.05$ for all precipitation levels; spruce: $\text{coef}=0.66$, $p<0.01$ for precipitation
158 level 3 and $\text{coef}=-0.4$, $p<0.05$ for precipitation level 4) sites (Table 2), resulting in less pronounced
159 differences between temperature levels at high precipitation. The creation of gaps increased mean
160 seedling emergence of both species (Fig. 1a and b), although there was substantial variation between
161 sites. The gap treatment strongly increased emergence at intermediate precipitation levels in both
162 alpine and intermediate sites (pine: $\text{coef}=0.90$, $p<0.001$ for precipitation level 2 and $\text{coef}=0.91$,
163 $p<0.001$ for precipitation level 3; spruce: $\text{coef}=0.62$, $p<0.05$ for precipitation level 2 and $\text{coef}=0.74$,
164 $p<0.01$ for precipitation level 3), () and was especially pronounced for pine at intermediate
165 temperature and precipitation ($\text{coef}=3.54$, $p < 0.01$ for precipitation level 2) (Table 2). Gap plots in the
166 sub-alpine sites with medium high site precipitation (level 3) had the highest number of seedlings per
167 plot for both species (Fig. 1a and b). Almost no seedlings emerged in the boreal sites in neither gap
168 nor intact vegetation plots (Fig. 1a and b).

169 The patterns for establishment followed the same overall trends as for emergence. The mean number
170 of established seedlings per plot in intact vegetation was higher in alpine than in sub-alpine sites (Fig.
171 1c and d), although most pronounced for pine ($\text{coef}=-2.58$, $p < 0.001$) (Table 2). Pine seedling
172 establishment increased significantly with site precipitation in the intermediate temperature sites
173 ($\text{coef}=1.51$, $p<0.05$ for precipitation level 3 and $\text{coef}= 3.05$, $p<0.001$ for precipitation level 4), but not
174 in the alpine sites ($p > 0.05$ for all precipitation levels) (Table 2), resulting in smaller differences in
175 establishment between temperature levels at high site precipitation. For spruce establishment there was
176 no interactive effect of temperature and precipitation on establishment, and seedling establishment
177 increased with site precipitation at both temperature levels ($\text{coef}=1.17$, $p<0.05$ for precipitation level 2,
178 $\text{coef}=2.01$, $p<0.001$ for precipitation level 3 and $\text{coef}=1.19$, $p<0.05$ for precipitation level 4) (Table 2).
179 For both species there was a tendency towards a peak in establishment at intermediate site
180 precipitation (Fig. 1c and d). Overall, the creation of gaps almost doubled mean seedling establishment
181 for both species (Fig. 1c and d). The effect of gap was higher on establishment than emergence, but
182 there was substantial variation among sites. The gap treatment increased seedling establishment of

183 pine in the alpine (coef=0.66, $p < 0.05$ for precipitation level 2, coef=0.88, $p < 0.01$ for precipitation
184 level 4), with a similar, although more pronounced, pattern in the sub-alpine sites (coef=3.78, $p < 0.01$
185 for precipitation level 2) (Table 2). Seedling establishment of spruce in gaps followed the same trend
186 as for pine, but was not significant ($p > 0.05$ for all tests) (Table 2). Very few seedlings had established
187 in the boreal sites (Fig. 1c and d), which was expected due to the low emergence, but a few “late
188 emergents” were detected in the last survey and were included in the establishment counts.

189 Both pine and spruce seedling height varied along the climate gradients. Spruce seedlings were
190 significantly taller in sub-alpine compared to alpine sites (coef=7.12, $p < 0.01$), and pine showed a
191 similar non-significant response ($p > 0.05$) (Fig. 2a and b). There were few significant effects of site
192 precipitation on height growth (Table 3). Seedlings were generally shorter in gaps than in intact
193 vegetation in both sub-alpine and alpine sites (pine: coef=-1.2, $p < 0.05$ for precipitation level 2 and
194 coef=-5.8, $p < 0.01$ for precipitation level 3; spruce: coef=-4.14, $p < 0.05$ across all precipitation levels)
195 (Fig. 2a and b and Table 3). The few spruce seedlings found in the boreal sites (the late emergents)
196 were among the tallest seedlings sampled (Fig. 2b).

197 Spruce seedling biomass was higher in sub-alpine compared to alpine sites (coef=0.88, $p < 0.05$), while
198 no significant difference was found for pine ($p > 0.05$), and there were few significant effects of site
199 precipitation on biomass (Fig. 2c and d and Table 3). Pine seedlings in gap plots had higher biomass
200 than those growing in intact vegetation in the sub-alpine sites (coef=0.75, $p < 0.01$) (Table 3), with a
201 similar tendency in the alpine (Fig. 2c). Spruce seedlings in gaps had higher biomass at both
202 temperature levels (coef=0.26 $p < 0.05$) (Table 3), with a tendency for greater differences in sub-alpine
203 sites (Fig. 2d).

204 Discussion

205 Contrary to our expectations, more tree seedlings emerged and established in the cold alpine sites
206 compared to the sub-alpine and boreal sites, indicating that low temperatures did not restrict seedling
207 recruitment of pine and spruce in the low-alpine zone in this study. This was an unexpected finding, as
208 the alpine sites are located well above the current tree line. Very few seedlings were found in the
209 boreal sites, which is surprising as these locations were characterized by well-developed conifer stands
210 and should in principle provide suitable microhabitats for tree seedling emergence and establishment.
211 Our findings contradict previous studies showing a dominant role of temperature for successful
212 establishment of trees (Tranquillini 1979; Payette 1985; Kullman and Engelmark 1990; Grace et al.
213 2002; Juntunen and Neuvonen 2006). Nonetheless, our results are in line with studies (e.g. Maher et
214 al. 2005; Batllori et al. 2009; Milbau et al. 2009) suggesting that other factors, such as biotic
215 interactions and precipitation, may be more important than low temperature as determinants of
216 successful tree seedling emergence and establishment also in alpine zones.

217 Site precipitation was an important factor for tree seedling recruitment within our study system, with
218 higher emergence and establishment at sites with intermediate and high precipitation. Soil moisture is
219 important for initiating germination mechanisms (e.g. Ibanez et al. 2007), and our findings align with
220 previous studies showing a positive effect of precipitation on seedling recruitment (McCarty 2001;
221 Walther et al. 2002). The tendency for a unimodal relationship with a decline in establishment in sites
222 with the lowest and highest precipitation may be due to drought in the dry continental end of the
223 precipitation gradient, and by hypoxic soil conditions in the wet oceanic end. Seedling survival at
224 medium-high precipitation sites may also be enhanced by high winter precipitation. While frost-
225 heaving has been reported to be among the most common causes of seedling damage and mortality
226 during the first winter, insulation by a deep snow cover can enhance winter survival (Erefur et al.
227 2008). The high over-winter survival of seedlings found in this study may thus be a result of a
228 protective snow cover during winter.

229 Whereas site temperature and precipitation was found to have an effect on tree seedling recruitment
230 success, interactions with the established vegetation also affected recruitment across the tree line
231 ecotone in this study. Gaps generally promoted seedling emergence and establishment in both sub-
232 alpine and alpine sites, as more seedlings were found in gaps compared to intact vegetation. Our
233 findings are in line with previous studies showing a clear benefit from gaps on recruitment (Berkowitz
234 et al. 1995; Gray and Spies 1996; Munier et al. 2010). Gap formation in the form of vegetation
235 removal can influence seedling recruitment by reducing aboveground competition and thereby
236 increasing light availability, but also by enhancing temperature fluctuations and nutrient levels (Graae
237 et al. 2011). We did not measure resource levels or microclimatic conditions in this study, and our
238 experiment thus cannot determine the mechanism behind the positive effect of gaps on seedling
239 recruitment. However, seedlings in gap plots were shorter than seedlings in intact vegetation, yet had
240 higher biomass, suggesting that removal of surrounding vegetation reduced competition for light. In
241 intact vegetation with intense competition for light seedlings potentially invest relatively more in
242 height growth at the expense of stability tissue like thicker stem and roots (Norgren 1996). Thus, it
243 seems that decreased competition, with a corresponding increase in light availability, may override
244 potential negative effects of gap such as increased vulnerability to injuries and damage (Munier et al.
245 2010) and drought- and temperature-related stress (Smith et al. 2003).

246 According to the stress-gradient hypothesis, the role of competition should decrease relative to
247 facilitation with decreasing abiotic stress, and facilitation should therefore be more important in alpine
248 than in sub-alpine and boreal habitats (Callaway et al. 2002). Our findings indicate that the positive
249 effect of gaps on seedling emergence and establishment, which could be due to lower competition,
250 was relatively more important than any facilitative effect of surrounding vegetation at all temperature
251 levels, including the alpine. Nonetheless, the difference in biomass between seedlings in gaps vs.
252 intact vegetation was larger in sub-alpine compared to alpine sites, which may suggest that
253 competition intensity increased with increasing temperature. Vegetation height increased with
254 increasing temperature, further suggesting that competition is more intense at high

255 temperatures. Even gaps were overgrown in some boreal sites (L. Tingstad, pers. obs.), which may
256 explain the almost complete lack of tree seedling recruitment in these sites.

257 Our findings suggest that competition may limit seedling emergence and establishment of pine and
258 spruce at the tree line ecotone, as indicated by the positive effect of gap formation on recruitment,
259 although the strength of the interactions seemed to vary with temperature and to a lesser degree with
260 precipitation. The finding that low temperature was not a limiting factor for the emergence and
261 establishment of pine and spruce seedlings, could indicate that climate warming may not directly
262 influence seedlings in the sub- and low-alpine zone of southern Norway. However, climate warming
263 may affect growth and survival of trees at later life stages. Previous studies have detected tree
264 seedlings above the tree line that rarely become mature, upright trees (Körner and Paulsen 2004;
265 Körner 2012). Seedlings in our study had a mean height of 2.45 cm and may have experienced a
266 thermal advantage of being short and hence sheltered by surrounding vegetation. Thus, although
267 climate warming may not enhance seedling recruitment *per se*, it may increase the number of
268 seedlings growing into tall trees, which can in turn lead to altitudinal advancement of the tree line.
269 Climate warming may also indirectly affect tree seedling recruitment by altering biotic interactions.
270 The role of competition in plant communities has been shown to increase with increasing temperature
271 (Klanderud 2005; Olsen and Klanderud 2014), and our findings suggest that more intense competition
272 in a warmer climate may, at least locally, reduce tree seedling emergence and establishment.
273 Disturbance, i.e. the formation of gaps, may thus become an increasingly important factor influencing
274 tree seedling recruitment also in alpine habitats, with a potential impact on future tree line position.

275

276 Acknowledgements

277 This project was partially funded by the Research Council of Norway through grants “NORKLIMA”
278 and “Klimaforsk”, project numbers 1849 12/S30 and 184636. We thank the land-owners for access to
279 the field sites and the whole SeedClim team for good collaboration and team-work in the field. We
280 also thank anonymous reviewers for helpful comments on the manuscript.

Table 1: Altitude and climatic characteristics of the twelve study sites. The sites were divided into three habitat types based on elevation a.s.l. and designated as alpine (Alp), sub-alpine (Sub) or boreal (Bor), within which four precipitation categories (1-4) were denoted based on mean annual precipitation (mm). Mean temperature of the four warmest months (tetraterm) (°C) and precipitation data were provided by the Norwegian Meteorological Institute

Site	Altitude	Temperature	Precipitation
	<i>m a.s.l.</i>	<i>tetraterm, °C</i>	<i>mm (mean annual)</i>
<i>Alpine</i>			
Alp1	1208	6.17	596
Alp2	1097	6.45	1321
Alp3	1213	5.87	1925
Alp4	1133	6.58	2725
<i>mean</i>	<i>1162</i>	<i>6.50</i>	
<i>Sub-alpine</i>			
Sub1	815	9.14	789
Sub2	700	9.17	1356
Sub3	770	8.77	1848
Sub4	780	8.67	3029
<i>mean</i>	<i>766</i>	<i>8.50</i>	
<i>Boreal</i>			
Bor1	589	10.33	600
Bor2	474	10.50	1161
Bor3	436	10.60	2043
Bor4	476	10.78	2923
<i>mean</i>	<i>493</i>	<i>10.50</i>	

Table 2: Model coefficients, standard errors (SE) and p-values of mixed effects models examining the effects of climate and gap formation on seedling emergence and establishment. Temperature is represented by sub-alpine (“Sub”) and precipitation by category number 2, 3 and 4 from dry to wet. Model coefficients reflect contrasts with the temperature category “Alp”, the precipitation category “1”, and the treatment category “intact vegetation” which are included in the intercept. * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$. ns= not significant.

Figure legends:

Fig. 1 Observed patterns of tree seedling emergence and establishment in the twelve study sites in response to presence (intact vegetation) or absence (gap) of vegetation: a) pine seedling emergence, b) spruce seedling emergence, c) pine seedling establishment and d) spruce seedling establishment. Habitat types correspond to the temperature gradient: alpine (Alp), sub-alpine (Sub) and boreal (Bor). The precipitation gradient is indicated with numbers 1-4 from dry to wet (see Table 1). Bars show means \pm SE, N=5

Fig. 2 Observed patterns of tree seedling height and aboveground biomass in the twelve study sites in response to presence (intact vegetation) or absence (gap) of vegetation: a) pine seedling height, b) spruce seedling height, c) pine seedling biomass, d) spruce seedling biomass. Habitat types correspond to the temperature gradient: alpine (Alp), sub-alpine (Sub) and boreal (Bor). The precipitation gradient is indicated with numbers 1-4 from dry to wet (see Table 1). Bars show means \pm SE. N=5
